(7) J. H. Espenson and D. W. Carlyle, *Inorg. Chem.*, **5**, 586 (1966). The reaction of  $\text{Cr}(\text{OH})_2\text{NH}_2^{3+}$  and  $\text{Cr}(\text{OH})_2^{3+}$  is not strictly an exchange reaction, since  $\text{NH}_3$  is released as an accompanying feature of the electron transfer. It is closely related to the other reactions, however, in which all but one of the ligands originally on Cr(III) are labilized upon its reduction to Cr(II). In the other instances these ligands are  $\text{H}_2\text{O}$ , however, and this change is not reflected in observable net chemical reaction. Recent experiments<sup>8,9</sup> have shown that halide complexes of chromium(III) undergo a chromium(II)-catalyzed aquation with a rate equation of the form  $k[\text{Cr}^{3+}][(\text{H}_2\text{O})_5\text{CrX}^{3+}]/[\text{H}^+]$ . This path presumably is a hydroxo-bridged process that releases the nonbridging  $\text{X}^-$  and is quite analogous to the reaction of  $(\text{H}_2\text{O})_5\text{CrNH}_2^{3+}$ .

tored 12–24 hr at  $-78^\circ$ , which apparently preserved the unchanged since the spectrum remained unaltered.

All experiments chromium(II) was labeled with chromium-51 tracer, obtained as a solution of chromium(III) chloride in 0.5 M hydrochloric acid. Labeled chromium(III) perchlorate stock solutions were prepared from ca. 0.1 F chromium(III) perchlorate solution to which had been added ca. 0.5 mcurie of  $^{51}\text{Cr}$  per 100 ml of solution. Chromium(III) was reduced electrolytically at a mercury electrode under purified nitrogen. The concentration of chloride introduced from the tracer solution by this technique was probably low (ca. 0.005 M).

Lithium perchlorate, used to adjust ionic strength, was prepared from lithium carbonate and perchloric acid and recrystallized three times.

Reagent grade perchloric acid was used without purification. Conductivity water, a double redistillation of laboratory distilled water from alkaline permanganate in a Barnstead still, was used in all solutions.

A Rex 50 W-X8 (50–100 mesh, Baker reagent grade) cation-exchange resin was washed with 4 F hydrochloric acid until free of Fe(II) (negative test with thiocyanate) and then allowed to stand overnight in the presence of excess sodium hydroxide and hydrogen peroxide. The resin was reconverted to the hydrogen ion form by repeated washing with 4 F hydrochloric acid. A finer particle size (200–400 mesh) was employed in the experiments used to determine the net charge on the chromium complex.

**Exchange Kinetics.** The procedures employed in the kinetic studies and separations are as follows. All reagents except chromium(II) were added to a 150-ml milk dilution bottle equipped with a sealing rubber cap which served as the reaction vessel. The solution was flushed with oxygen-free nitrogen for at least 30 min; chromium(II) was introduced by syringe. Samples were withdrawn by syringe at appropriate intervals and quenched in a stream of water which oxidized chromium(II) to  $\text{Cr}_2(\text{OH})_2^{4+}$ , a dimeric form of chromium(III).<sup>11</sup> (Sample volumes generally were 1–3 ml but were not measured or controlled accurately since the specific activity was the quantity being measured.)

**Ion-exchange separation of  $\text{CrH}_2\text{PO}_3^{2+}$  from  $\text{Cr}_2(\text{OH})_2^{4+}$ .** In 16 experiments only  $\text{Cr}^{2+}$  activity was followed, and in 14 experiments only  $\text{CrH}_2\text{PO}_3^{2+}$ . In an additional five experiments both activities were followed. Thus a total of 30 rate constants were measured. The air-quenched sample was transferred to a 1 mm  $\times$  8 cm column of resin in the hydrogen ion form, contained in a short length of Tygon tubing, and eluted with 2 F perchloric acid. The first 7–8 ml of solution contained most of the hypophosphite complex, the specific activity of which was determined by counting a standard volume of the sample in a well-type scintillation counter and spectrophotometrically analyzing chromium as chromate ion in alkaline solution after oxidation with hydrogen peroxide. In experiments where the chromium(II) activity was followed with time, the column was first rinsed with 3 ml of 2 F perchloric acid to remove all chromium species but  $\text{H}_2\text{PO}_3^{2+}$ , which then was removed from the resin by treatment with sodium hydroxide and hydrogen peroxide. The specific activity of chromium in the resulting solution was determined as follows.

Chromium(II) in each reaction solution was analyzed directly by spectrophotometric determination of the cobalt(II) produced by reaction with a small excess of pentaamminechlorocobalt(III) ion.<sup>12</sup> In two to four samples were withdrawn for analysis during the course of a run.

**Results**

**Net Ionic Charge.** The unexpected results found for the effect of hydrogen ion on the electron-exchange rate (see below) led us to reconsider the composition of the hypophosphite complex, previously formulated as  $\text{CrH}_2\text{PO}_3^{2+}$ . Earlier work<sup>10</sup> had established a 1:1 ratio of phosphorus and chromium in the complex, and the qualitative behavior of this species on cation-exchange resin indicated the species had a net charge 2+ in 1 F solutions of either perchloric or lithium perchlorate.

M. Ardon and R. A. Plane, *J. Am. Chem. Soc.*, **81**, 3197 (1959). This reduction technique for chromium(II) analysis was employed by B. Zabin and H. Taube, *Inorg. Chem.*, **3**, 968 (1964). The spectrophotometric analysis of cobalt(II) has been described previously: Espenson, *ibid.*, **4**, 1025 (1965).

Ion-exchange equilibration experiments of the type developed by Cady and Connick<sup>13</sup> were carried out to determine unambiguously the ionic charge on the hypophosphite complex. A low concentration of the species of interest was equilibrated with cation-exchange resin at two known hydrogen ion concentrations, 1 and 0.5 M. The presumed constancy of the equilibrium quotient for reaction 3 (overline = resin phase) on changing from 1 to 0.5 M  $\text{H}^+$  allows computation of  $b$  from equilibrations with the same resin at two  $[\text{H}^+]$

values. Precision of the method is limited by variation of the charge  $b$  from integral values, which may be caused by a change in the value of the equilibrium quotient for reaction 3 in 1 F compared to 0.5 F perchloric acid solution. A changing degree of protonation of the complex over this range of  $[\text{H}^+]$  also would give nonintegral values. Hexaquo-chromium(III) was carried through some experiments as a check on the procedure. The results for this ion and for hypophosphitochromium(III) are presented in Table I. The

Table I. Net Ionic Charge on Chromium(III) Species

Total Cr(III), mmole <sup>a,b</sup>	$[\text{H}^+]$ , M	Vol, ml	$[\text{Cr(III)}]$ , $\text{M} \times 10^3$	Charge
A. Hexaquo-chromium(III) Ion				
0.432	0.980	120	0.935	2.94
0.413	0.490	200	0.1528	
0.432	1.012	60	1.271	2.95
0.419	0.506	100	0.1920	
B. Hypophosphitochromium(III) Ion

0.397	0.525	100	1.294	

<sup>a</sup> The difference in the amount of total chromium between the first and second parts of an experiment reflects the amount removed for analysis of the first concentration. This removal of solution also accounts for the relation of  $[\text{H}^+]$  and volume. <sup>b</sup> In the various experiments, between 3.45 and 3.57 g of resin, with a capacity of 3.55 mmole of  $\text{H}^+$  per gram, was used.

charge value found (2.94) for hexaquo-chromium(III) is close to the value found by Cady and Connick (2.89).<sup>13</sup> The value (average 2.11) determined for hypophosphitochromium(III) is slightly larger than the integral +2 value presumed for  $\text{CrH}_2\text{PO}_3^{2+}$ . Although the value is not an integer, this does not seem to constitute compelling evidence that the true charge on the hypophosphite complex is not +2. Since the kinetic evidence presented later indicates that almost certainly only a single species predominates over the range 0.026–1 M  $\text{H}^+$ , the conclusion seems justified that this species is the dipositive ion  $\text{CrH}_2\text{PO}_3^{2+}$ , as in the original formulation.<sup>10</sup>

**Exchange Rate Law.** Where chromium(II) specific activity was followed with time, the McKay equation

(13) H. H. Cady and R. E. Connick, *J. Am. Chem. Soc.*, **80**, 2646 (1958).

Figure 1. Illustrating McKay plots (eq 4) in a typical exchange experiment with the concentrations shown. The points represent  $\text{Cr}^{3+}$  sampling (+) and  $\text{CrH}_2\text{PO}_3^{2+}$  sampling (O). The straight lines have slopes given by the computer calculated rate constants and correspond to half-times of 42.5 (+) and 44.3 min (O). The rate constants are  $10^3 k_2 = 5.80 \pm 0.59 \text{ M}^{-1} \text{ sec}^{-1}$  (+) and  $6.04 \pm 0.60 \text{ M}^{-1} \text{ sec}^{-1}$  (O), where the uncertainties represent the standard deviation of  $k_2$ .

tion<sup>14</sup> takes the form given in eq 4 in which  $S$  stands

$$d \ln \frac{S_t - S_\infty}{S_0 - S_\infty} = -R \frac{[\text{Cr}^{3+}] + [\text{CrH}_2\text{PO}_3^{2+}]}{[\text{Cr}^{3+}][\text{CrH}_2\text{PO}_3^{2+}]} dt \quad (4)$$

for specific activity of chromium(II), counts per minute per millimole, and  $R$  represents the rate law for exchange. An analogous equation with  $S_0 = 0$  holds for runs where the activity of  $\text{CrH}_2\text{PO}_3^{2+}$  was measured. As a working hypothesis we assumed that, at constant  $[\text{H}^+]$ , the rate of electron exchange is first order in each chromium species according to

$$R = k_2 [\text{Cr}^{3+}][\text{CrH}_2\text{PO}_3^{2+}] \quad (5)$$

A nonlinear, least-squares computer program<sup>15</sup> was used to fit the exchange data in each run to eq 4 and 5. This program calculated  $R$  or  $k_2$ , and also the "best" values of  $S_0$  and  $S_\infty$ . This fit for  $S_\infty$  is preferable to the experimental value, since secondary reactions set in at long times.<sup>16,17</sup> Data from a typical run in which

(14) H. A. C. McKay, *Nature*, **142**, 997 (1938).

(15) This program is based on a report from Los Alamos Scientific Laboratory, LA2367 + Addenda. We are grateful to Drs. T. W. Newton and R. H. Moore for supplying us with the computer programs and to Mr. J. P. Birk for adapting them to the IBM 360 computing facilities.

(16) Spontaneous aquation of the metastable hypophosphite complex must be considered. This reaction becomes an important factor in exchange runs only at high  $[\text{H}^+]$ , however, since its rate varies as  $[\text{H}^+]$ , whereas the exchange rate varies as  $[\text{H}^+]^{-1}$ . Any interference from appreciable spontaneous aquation during an exchange run would result in a higher value of the calculated exchange rate constant. Of course, aquation, after exchange is substantially complete, has no effect. The  $\text{Cr}^{3+}$  that is the product of aquation would be collected with neither of the separated exchanging species. In one experiment with relatively low  $[\text{Cr}^{3+}]$ ,  $1.8 \times 10^{-3} \text{ M}$ , and  $0.95 \text{ M H}^+$ , the rates of aquation and exchange were comparable, and in another run exchange was only twice as fast as aquation. In all other experiments the effect of aquation was smaller, generally a good deal smaller.

Figure 2. Illustrating the relation of  $k_2$  and  $[\text{H}^+]$  in a log-log plot. The lines drawn through the points have a slope of  $-1$ .

both chromium(II) and the hypophosphitochromium(III) complex were followed are shown in Figure 1. For the run shown here, the two sampling techniques gave rate constants that agreed to within an average deviation of 2%. In the four other such pairs of determinations, average deviations were 0.1, 0.3, 4.3, and 12%, and no systematic bias of the direction of the deviation and the oxidation state sampled was noted.

Exchange experiments at  $25.0^\circ$  covered these concentrations:  $\text{Cr}^{3+}$ ,  $0.18\text{--}2.5 \times 10^{-3} \text{ M}$ ;  $\text{CrH}_2\text{PO}_3^{2+}$ ,  $0.37\text{--}4.0 \times 10^{-3} \text{ M}$ . Every experiment fit the McKay equation, and constancy of the calculated  $k_2$  at a particular  $[\text{H}^+]$  confirmed the second-order exchange rate law shown in eq 5. The average of the standard deviations in 22 runs at  $25.0^\circ$  was 8.5%. When eight additional values at other temperatures were included as well, it was 8.9%.

**Effect of Hydrogen Ion.** Exchange experiments were carried out at several hydrogen ion concentrations in the range  $0.026\text{--}1.0 \text{ M}$ . Hydrogen ion exerted a strong inverse effect on the reaction rate. Figure 2 shows the variation of  $k_2$ , the pseudo-second-order rate constant, plotted vs.  $[\text{H}^+]$  on a log-log scale.

(17) In eight runs at low  $[\text{H}^+]$ ,  $<0.16 \text{ M}$ , samples were taken at sufficiently long times to enable comparison of observed values of  $S_\infty$  with those calculated by the computer fit of the data. The average deviation of observed and fitted  $S_\infty$  values was 1.9% in these eight runs, justifying the procedure used. In principle  $S_0$  and  $S_\infty$  are given by the solution composition. Loss of small amounts of chromium(II) by air oxidation prior to exchange, however, causes this to be a distinctly less attractive procedure. The extent of such loss of  $^\circ\text{Cr}$  to exchange could be estimated roughly from the chromium(II) analyses. These corrections were extremely imprecise; they did show, however, that the observed  $S_0$  and  $S_\infty$  values were in reasonable agreement with those calculated from the composition and the amount of chromium(II) converted to the non-exchanging dimer.

data are consistent with a rate equation containing a single term<sup>18</sup> inversely proportional to  $[H^+]$ . The unweighted average value of  $10^4k$  ( $\text{sec}^{-1}$ )

$$\text{exchange rate} = k[\text{Cr}^{3+}][\text{CrH}_2\text{PO}_4^{2+}]/[H^+] \quad (6)$$

is  $6.26 (\pm 0.87 \text{ std dev})$ . A weighted average instant expresses the results more meaningfully. Each value is weighted by the computer-calculated standard deviation of  $k$  between observed and calculated values of specific activities fit to the McKay plot. With this weighting, the average value of  $10^4k$  ( $\text{sec}^{-1}$ ) is  $6.11 (\pm 0.84 \text{ std dev})$ . The effect of this weighting procedure is to count most heavily those runs where the scatter in the data was lowest, and where the precision was obtained.

**Temperature Dependence.** The exchange rate was studied at two other temperatures, 16.0 and 35.0°. Values<sup>19</sup> of  $10^4k$  (eq 6) are as follows: 35.0°,  $\text{Cr}^{3+}$  sampling only,  $18.3 \text{ sec}^{-1} (\pm 1.1 \text{ std dev})$ , and 16.0°,  $\text{Cr}^{3+}$  sampling only,  $2.08 \text{ sec}^{-1} (\pm 0.1 \text{ std dev})$ , four runs. When these values are recalculated as at 25.0°,  $10^4k$  ( $\text{sec}^{-1}$ ) =  $18.5 \pm 1.0$  and  $2.10$

and the enthalpy and entropy of activation were calculated from the 30 individual rate constants according to the absolute rate theory expression with  $\kappa = 1$ . The primary weighting procedure in the least-squares method for the rate constants would be a weight of  $1/k^2$ , but the per cent accuracy is presumed to be the same at each temperature. We have chosen a weighting where the precision of each run is taken into account; here each value is weighted as  $1/k\sigma_k$  where  $\sigma_k$  is the standard deviation in  $k$ , as generated by the fit to the data in that particular run. On this basis the activation parameters and their standard deviations are  $\Delta H^\ddagger = 19.7 \pm 1.0 \text{ kcal mole}^{-1}$  and  $\Delta S^\ddagger = -7.2 \text{ eu}$ . Rate constants ( $10^4k$ ,  $\text{sec}^{-1}$ ) recalculated as parameters at 16.0, 25.0, and 35.0° are 2.073, 6.11, and 18.29, compared to the individual averages at temperatures of 2.10, 6.11, and 18.5.

ON

**Structure of Hypophosphitochromium(III) Ion.** The structure of the  $(\text{H}_2\text{O})_5\text{CrH}_2\text{PO}_4^{2+}$  was determined by the question remains of the structure of the coordinated anion in this complex. Consider the formulas  $(\text{H}_2\text{O})_5\text{Cr}(\text{OPH}_2\text{O})^{2+}$  and  $(\text{H}_2\text{O})_5\text{Cr}(\text{H}_2\text{PO}_4)^{2+}$ . Hypophosphorous acid is a monobasic acid which coordination number four for phosphorus is reserved; its formula is  $\text{HOPH}_2\text{O}$ . Consideration of the evidence has been noted for a second and

alternative dependences on  $[H^+]$  were considered including proportional to  $[H^+]^0$  and/or  $[H^+]^{-1}$ . The fit of the data was improved by such terms, and the values of the rate constants were generally within a standard deviation of zero. In 25.0°, the rate law  $k[H^+]^{-1} + k'$  had values  $10^4k = 6.04 \pm 1.1$  and  $10^4k' = -1.1 \pm 5.2 \text{ M}^{-1} \text{ sec}^{-1}$ . The same data in the form  $k[H^+]^{-1} + k''[H^+]^0$  gave values  $10^4k = 5.8 \pm 0.23 \text{ sec}^{-1}$  and  $10^4k'' = 1.6 \pm 1.5 \text{ M sec}^{-1}$ . For these three equations, the weighted fit of the data was as follows:  $k$  only, 0.32;  $k$  and  $k'$ , 0.32;  $k$  and  $k''$ , 0.32. These results led us to conclude that a single term in  $[H^+]^{-1}$  is consistent with these data.

Tabulation of the individual exchange experiments listing conditions and time, fraction exchange has been deposited as Document 9357 with the ADI Auxiliary Publications Project, Photoduplication Service, Library of Congress, Washington, D. C. 20540. It may be secured by citing the document number and remitting \$1.25 for 35-mm microfilm. Advance payment is required. Make checks or money orders payable to: Chief, Photoduplication Service, Library of Congress.

more reactive form of the acid which plays an important role in a number of oxidation reactions<sup>20</sup> of hypophosphorous acid and also in the exchange reaction<sup>21</sup> of the nonacidic protons. The rate-limiting step in these reactions involves only hypophosphorous acid (and an acid catalyst), in which a structural rearrangement is presumed (eq 7). The latter structure is by far the less

stable; various estimates<sup>20,21</sup> give the equilibrium quotient of this structural change reaction as  $10^{-9}$ – $10^{-12}$ .

A postulated isomeric structure  $\text{Cr}(\text{OPHOH})^{2+}$  for the complex raises questions both of its rate of formation and of its stability. The rate of reaction of  $\text{Cr}^{3+}$  and  $\text{H}_2\text{PO}_4$  is sufficiently low to be consistent<sup>22</sup> with estimates of the rate of reaction 7, but the intrinsic stability required to enable the species  $(\text{H}_2\text{O})_5\text{Cr}(\text{OPHOH})^{2+}$  to form in preference to  $(\text{H}_2\text{O})_5\text{Cr}(\text{OPH}_2\text{O})^{2+}$  in spite of the  $\sim 15 \text{ kcal}$  by which  $\text{HOPH}_2\text{O}$  is favored over  $(\text{HO})_2\text{PH}$  seems larger than the free energies available for most Cr(III) complexes. It is difficult to rule out the form  $(\text{H}_2\text{O})_5(\text{OPHOH})^{2+}$  on this basis, however, since stability constants for species of known structure are not available. The noncommittal representation  $\text{CrH}_2\text{PO}_4^{2+}$  will be used in the discussion that follows except when points of detailed structure must be raised.

**Exchange Mechanism.** Electron exchange of chromium(II) and hypophosphitochromium(III) ions proceeds without release of hypophosphite ion from the primary coordination sphere of chromium(III). The reaction necessarily involves bridging by this anionic ligand similar to other exchange reactions of  $(\text{H}_2\text{O})_5\text{CrX}^{2+}$ .<sup>2-7</sup> Replacement of  $X^-$  by a water molecule (eq 8) is in most instances (including  $X^- = \text{H}_2\text{PO}_4^-$ )

a thermodynamically favored process, but its spontaneous rate is so low that it is not a major reaction during the time in which Cr(II)–(III) exchange occurs.<sup>18</sup> The feature that electron transfer and  $X^-$  transfer proceed at identical rates constitutes an interesting and significant aspect of the mechanism of these reactions.

The energy of the two exchange sites must first become equivalent before electron exchange occurs.<sup>23</sup> A mechanism for this energy equalization is the formation of a symmetrical transition state. The exchange reaction of  $(\text{H}_2\text{O})_5\text{CrH}_2\text{PO}_4^{2+}$  and  $\text{Cr}(\text{H}_2\text{O})_6^{3+}$  would appear to have available an inner-sphere transition state that maintains symmetry at each chromium atom

(20) (a) R. O. Griffith and A. McKeown, *Trans. Faraday Soc.*, **30**, 530 (1934); (b) R. O. Griffith, A. McKeown, and R. P. Taylor, *ibid.*, **36**, 752 (1940); (c) P. Hayward and D. M. Yost, *J. Am. Chem. Soc.*, **71**, 915 (1949).

(21) W. A. Jenkins and D. M. Yost, *J. Inorg. Nucl. Chem.*, **11**, 297 (1959). This article contains a review of  $\text{H}_2\text{PO}_4$  reaction mechanisms and demonstrates the interrelation of H exchange and oxidation-reduction reactions.

(22) The rate of the transformation in eq 7 is of the form  $k_{\text{HA}}[\text{H}_2\text{PO}_4][\text{HA}]$  in which HA is an acid catalyst.<sup>21</sup> If the complex formation rate constant<sup>19</sup>  $k_d[\text{H}_2\text{PO}_4][\text{Cr}^{3+}]$  is regarded as a rate constant of this type, its value ( $0.2 \text{ M}^{-1} \text{ hr}^{-1}$ ) does not appear unreasonable for  $\text{Cr}^{3+} + \text{HA}$  in view of the acid strength of  $\text{Cr}^{3+}$  relative to other HA catalysts studied previously.<sup>21</sup>

(23) W. F. Libby, *J. Phys. Chem.*, **56**, 863 (1952).

This transition state could be formed from the reactants with an apparent minimum of structural reorganization. Over the entire range of  $[H^+]$  studied here, even at 1 M  $H^+$ , this symmetrical transition state remains quite an unimportant pathway,<sup>16</sup> relative to a configuration containing one proton less. The net activation process, written to ignore the role of solvent molecules, is given by eq 9.

Three reasonable formulations for this transition state that we wish to consider are shown in Scheme I. Since during exchange hypophosphite ion is transferred, and not replaced by water, only transition states with a bridging hypophosphite ion are considered. The three formulations are a nonsymmetrical transition state (A) containing a nonbridging hydroxide ion ligand, a symmetrical configuration (B) involving (formally,

Scheme I

at least) proton loss from phosphorus, and a symmetrical double-bridged structure (C). The kinetic results we have obtained do not alone allow us to eliminate any of the kinetically equivalent alternatives; the discussion that follows is based largely on analogy with other exchange reactions and on the properties of hypophosphite ion.

The nonsymmetrical transition state (A) has no known counterpart in other Cr(II)–Cr(III) exchanges. Rate laws of this form were noted<sup>7–9</sup> for some reactions of  $(H_2O)_5CrX^{2+}$  and  $Cr^{2+}$ . These reactions result in aquation of X and not its transfer, however; presumably hydroxide ion is a bridging ligand in these cases, and the nonbridging  $X^-$  group aquates upon electron transfer. Formulation A suffers from the further disadvantage that it is not symmetrical. Symmetry is not a criterion for a suitable exchange transition state, but it generally does provide the best mechanism for bringing about energy equivalence of the two electron exchange sites.<sup>22</sup> On the basis of these arguments we are inclined to regard A as a relatively improbable configuration for the transition state.

Formulation B involves a significant structural change in the reactant hypophosphite complex. The phosphorus protons in the free acid are nonlabile, and it seems unlikely those on the coordinated anion are substantially more so. Thus this mechanism cannot be a rapid acid dissociation equilibrium of a P–H proton in the complex  $(H_2O)_5Cr(OPH_2O)^{2+}$ . Were the pre-

viously considered isomeric complex  $Cr(OPHOH)^{2+}$  the predominant form, the symmetric formulation B would be easily understood. Since this structure for the hypophosphite complex was deemed the less likely, B seems relatively improbable unless further studies on the complex reveal its structure.

Formulation C, a double-bridged transition state involving the anion  $H_2PO_3^-$  and one *cis* hydroxide ion, is also consistent with all evidence now at hand. This formulation preserves symmetry in the transition state, accounts for the observed rate dependence on  $[H^+]^{-1}$ , and would involve a rapid preequilibrium loss of a labile proton from coordinated water.

Direct evidence for double-bridged transition states has been found only for *cis*-diazido complexes.<sup>24,25</sup> They have been shown to be unimportant in some other instances, including difluoro<sup>8</sup> and diaquo complexes.<sup>26</sup> Doubly bridged transition states employing hydroxide ion analogous to C have also been suggested for the rate terms varying as  $[H^+]^{-1}$  in the reaction of  $CrSCN^{2+}$  and  $Cr^{2+}$ ,<sup>27</sup> and in the reaction of *cis*- $Co(NH_3)_4(OH_2)(O_2CCH_3)^{2+}$  and  $Cr^{2+}$ .<sup>28</sup> Preliminary work on *cis*- $Cr(H_2PO_3)_2^+$  +  $Cr^{2+}$  indicates important contributions of a double-bridged transition state.<sup>29</sup>

**Related Reactions.** Since the form of the rate law for this reaction differs from that in previously studied Cr(II)–Cr(III) exchange reactions involving  $Cr^{III}$ –X–complexes, a comparison of the kinetic parameters cannot be made. The exchange reactions  $Cr^{2+}$ – $Cr^{3+}$  and  $CrNH_3^{2+}$ – $Cr^{3+}$  each have a rate law of the form  $[Cr^{III}][Cr^{2+}]/[H^+]$ , analogous to the present results.<sup>7–9</sup> In those instances, however, presumably the transition states involve hydroxide ion bridging, which is certainly not the case in the present reaction.

Further information on the mechanism of the exchange reaction will be obtained from studies on the kinetics and equilibrium of iron(III)–hypophosphite ion complex formation. Since complex formation would be rapid relative to isomerization of hypophosphorous acid, the kinetics and equilibrium of this reaction may point up some important differences related to the structural features. In addition, alternate syntheses of chromium(III) hypophosphite complex using relatively rapid reactions (e.g., oxidation–reduction techniques) may clarify the question of the possibility of two forms of the monohypophosphite complex.

More directly, the use of labeled hypophosphorous acid (i.e., tritium labeling of  $H_2PO_3$  as in the studies of Jenkins and Yost<sup>31</sup>) may clarify many points. An answer to the question of whether one of the two “non-exchangeable” hydrogens is exchanged on complex formation or on electron exchange or not at all can provide valuable information both on the structure of the complex and on the exchange mechanism not available at present. The preferred formulation (C) causes transfer of one water oxygen as well, but oxygen-18 labeling will not be a useful technique since repeated exchange will cause all *cis* and *trans* oxygens in the complex to exchange.

# The Oxidation of Water by Cobaltic Aquo Ions

Michael Anbar and Israel Pecht

Contribution from the Weizmann Institute of Science, Rehovoth, Israel.

Received December 6, 1966

**Abstract:** The oxidation of water to oxygen by  $\text{Co(III)}_{\text{aq}}$  has been investigated using  $\text{O}^{18}$  as tracer. It has been shown that the oxidation reaction, which proceeds by inner-sphere ligand to metal electron transfer, involves the oxidation of a  $\text{Co(III)}_{\text{aq}}$  dimer by a  $\text{Co}_{\text{aq}}^{3+}$  ion. The  $\text{HO}_2$  radical, which is being formed in the rate-determining step, is therefore the immediate precursor of molecular oxygen.  $\text{Co(III)}_{\text{aq}}$  was shown to contain substantial amounts of dimers even in strongly acid solutions.

Cobaltic aquo ions in aqueous solution are known to oxidize water to oxygen. The kinetics of this reaction have been studied by several investigators;<sup>1-3</sup> however, the mechanism of this reaction has not been to unequivocally elucidated.<sup>4</sup> Mechanisms proposed for this reaction have been based solely on kinetic evidence, on which conflicting information is available.<sup>4</sup> Thermodynamic grounds it may be inferred that the primary step of oxidation of water to oxygen by  $\text{Co(III)}_{\text{aq}}$  does not involve a single electron transfer, the reaction  $\text{Co(III)}_{\text{aq}} + \text{H}_2\text{O} \rightarrow \text{Co(II)}_{\text{aq}} + \text{OH}$  has a positive free energy of about 24 kcal/mole.<sup>5,6</sup> An alternative primary product is hydrogen peroxide produced by the concerted reduction of two  $\text{Co(III)}_{\text{aq}}$  ions. Kinetics of reduction of  $\text{Co(III)}_{\text{aq}}$  by water as intercalated by Bawn and White<sup>2</sup> support a bimolecular pathway; however, no experimental evidence for the formation of  $\text{H}_2\text{O}_2$  as a primary product of oxidation of water is available. A third possibility suggested by Baxendale in interpretation of the kinetic data<sup>3</sup> is the formation of a primary product by the oxidation of a  $\text{Co(III)}_{\text{aq}}$  by  $\text{Co}_{\text{aq}}^{3+}$ . This mechanism is thermodynamically more favorable than the former one by a  $\Delta F$  of about 3 kcal/mole.<sup>5,6</sup> Another open question is whether hydrogen peroxide, if formed, are produced by an inner-sphere electron transfer from the ligand<sup>7-9</sup> or by an outer-sphere oxidation of the solvent molecules. By the use of  $\text{O}^{18}$  as tracer, we were able to show that  $\text{HO}_2$  is produced as primary product in the oxidation of water by  $\text{Co(III)}_{\text{aq}}$  and that this reaction proceeds by an inner-sphere oxidation of water bound to the metal.

## Experimental Section

**Reagents.** Oxygen-18 enriched water was supplied by the separation plant of the Weizmann Institute of Science. It was distilled several times over alkaline permanganate in an all-glass apparatus.  $\text{Co(ClO}_4)_3$  (reagent grade, G. F. Smith Chemical Co., Columbus, Ohio) and hydrogen peroxide 50% (Analar grade, Riedel, Germany) were used.

B.D.H.) were used. Triply distilled water was used throughout this study.

$\text{Co(III)}_{\text{aq}}$  solutions were prepared by electrolytic oxidation of 0.6 M  $\text{Co(ClO}_4)_3$  in 6 M  $\text{HClO}_4$  at 0°. The electrolysis (current density of 300 ma/cm<sup>2</sup>) was carried out in a cell consisting of a platinum anode inside a nonglazed ceramic vessel surrounded by a copper foil cathode. The solution was electrolyzed for 2 hr, i.e., considerable time after the oxidation of  $\text{Co(II)}$  was complete. As soon as the electrolytic oxidation was stopped, the  $\text{Co(III)}_{\text{aq}}$  solution was frozen in liquid nitrogen and kept as such until used. The  $\text{Co(II)}$  content of the  $\text{Co(III)}$  solutions prepared by this method is negligible.

$\text{Co(III)}_{\text{aq}}$  labeled with  $^{18}\text{O}$  was prepared by the same method using  $\text{H}_2^{18}\text{O}$  (~70 atom %  $^{18}\text{O}$ ) as solvent.

**Methods.** One milliliter of the concentrated stock solution of  $\text{Co(III)}_{\text{aq}}$  (0.6 M) enriched in  $^{18}\text{O}$  was mixed under vacuum at room temperature (22–24°) with 20 ml of degassed, triply distilled water of natural  $^{18}\text{O}$  content. Any oxygen dissolved, or formed in the  $\text{Co(III)}_{\text{aq}}$  solution, was quantitatively removed before mixing by continuous pumping from the two solutions until the moment of mixing. The oxygen formed after mixing was completely pumped off by a Toepler pump at predetermined time intervals (3, 6, 10, 30, 120, and 360 min following time of mixing), and its isotopic composition was mass-spectrometrically analyzed. Masses 28 and 40 were also measured to check on air contamination. The experiments were repeated using  $\text{Co(III)}_{\text{aq}}$  of natural  $^{18}\text{O}$  content mixed with water enriched in  $^{18}\text{O}$ .

The experiments designed for detection of the intermediary formation of hydrogen peroxide were carried out as follows: 50  $\mu\text{l}$  of 0.6 M  $\text{Co(III)}_{\text{aq}}$  stock solution were injected through a serological cap into 250 ml of  $10^{-4}$  M  $\text{H}_2\text{O}_2$  solution, thoroughly degassed, and vigorously stirred. The isotopic composition of the solvent water was different from that of the coordination sphere of  $\text{Co(III)}_{\text{aq}}$ ; the  $\text{H}_2\text{O}_2$  was of natural isotopic composition. The acidity of the reaction mixture was preadjusted by NaOH to give a final pH of ~4. After the reaction was complete the molecular oxygen formed was pumped off for isotopic analysis. The solution was then thoroughly degassed, and the residual hydrogen peroxide was decomposed by injecting either a suspension of platinum black in water or a solution of ceric ions. The  $\text{O}_2$  produced from the residual  $\text{H}_2\text{O}_2$  was then analyzed for its isotopic composition.

## Results and Discussion

The working hypothesis of this study was that the oxidation of water by  $\text{Co(III)}_{\text{aq}}$  proceeds by an inner-sphere electron transfer from the coordinated ligand water to the central ion. This hypothesis could be proven by demonstrating that the molecular oxygen formed originates from water molecules bound to the metal ion in the inner coordination sphere. Cobaltic ions are known to form substitution inert complexes.<sup>10</sup> The  $\text{Co(III)}_{\text{aq}}-\text{H}_2\text{O}$  isotopic exchange has been estimated to be a relatively slow process<sup>10</sup> unless  $\text{Co(II)}_{\text{aq}}$  ions are present; these may catalyze the water exchange by  $\text{Co(III)}_{\text{aq}}-\text{Co(II)}_{\text{aq}}$  electron exchange.<sup>11</sup> It seemed plausible therefore that when the aquo complex of  $\text{Co(III)}$  labeled with  $^{18}\text{O}$  reacts with  $\text{H}_2^{16}\text{O}$ , the rate of

ligand oxidation might compete with that of ligand exchange resulting in the formation of molecular oxygen partly labeled with <sup>18</sup>O. To check on these assumptions we have treated <sup>18</sup>O labeled Co(III)<sub>aq</sub> with H<sub>2</sub><sup>18</sup>O and determined the <sup>18</sup>O content of the oxygen formed. As there are no reliable data available on the rate of the Co(III)<sub>aq</sub>-H<sub>2</sub>O isotopic exchange, it was impossible to predict the relative rates of isotopic exchange *vs.* oxidation of water *a priori*.

It has been found that (6.65 - 2.6)/65 = 6.2% of the oxygen evolved originates from the inner coordination sphere of Co(III)<sub>aq</sub>. This result could be interpreted in two ways: either that 6.2% of the reaction proceeds by an inner-sphere oxidation mechanism and the rest by an outer-sphere process, or that all the oxygen formed originates from the ligand water but that an over-all average of 93.8% of the ligand H<sub>2</sub><sup>18</sup>O has exchanged with the solvent before oxidation. The second interpretation seems to be much more plausible in view of the <sup>18</sup>O content of O<sub>2</sub> collected in successive fractions during the reaction of Co(III)<sub>aq</sub> with water (Table I). It may be seen that, whereas the first fraction collected contains up to half of the oxygen originating from the inner sphere, the last fractions collected have an isotopic composition identical with that of the solvent. These findings show that the relatively low yield of <sup>18</sup>O in the molecular oxygen formed is due to H<sub>2</sub>O<sub>solvent</sub>-H<sub>2</sub>O<sub>ligand</sub> isotopic exchange, and that it is very likely that all the oxygen evolved originates from the inner sphere of hydration. It is experimentally hard to sample oxygen at the very early stages of Co(III)<sub>aq</sub> decomposition, which could allow the isotopic composition of the evolved oxygen at time zero to be obtained. Thus a small contribution (<5%) of an outer-sphere mechanism cannot be completely excluded.

In view of the competition between the ligand exchange and ligand oxidation it was of interest to examine the exact isotopic distribution of <sup>18</sup>O in the oxygen molecules produced. We have examined therefore the isotopic distribution of <sup>18</sup>O between <sup>18</sup>,<sup>16</sup>O<sub>2</sub>

and <sup>16</sup>,<sup>16</sup>O<sub>2</sub> and found it to be far from the statistical: [<sup>16</sup>,<sup>18</sup>O<sub>2</sub>]/[<sup>18</sup>,<sup>18</sup>O<sub>2</sub>][<sup>16</sup>,<sup>16</sup>O<sub>2</sub>] = 4.<sup>12</sup> If the O<sub>2</sub> formed originated from two Co(III)<sub>aq</sub> ions labeled with <sup>18</sup>O, the oxygen should contain <sup>18</sup>,<sup>18</sup>O<sub>2</sub>. However, in view of the extensive isotopic exchange, it seemed improbable that <sup>18</sup>,<sup>18</sup>O<sub>2</sub> would be formed in any appreciable amount if the oxygen originated from the reaction between two separate Co(H<sub>2</sub>O)<sub>6</sub><sup>3+</sup> ions. On the other hand, if the <sup>18</sup>,<sup>18</sup>O<sub>2</sub> would originate from H<sub>2</sub><sup>18</sup>O labeled Co(III)<sub>aq</sub> in a chemical form which does not readily undergo isotopic exchange with the solvent, one could calculate the isotopic distribution of <sup>16</sup>,<sup>16</sup>O<sub>2</sub>, <sup>16</sup>,<sup>18</sup>O<sub>2</sub>, and <sup>18</sup>,<sup>18</sup>O<sub>2</sub> assuming that the evolved O<sub>2</sub> originates from two sources: O<sub>2</sub> labeled with <sup>18</sup>O formed from the labeled Co(III)<sub>aq</sub> exclusively and the rest of the O<sub>2</sub> from the water exclusively. Following this assumption the mole fractions of <sup>16</sup>,<sup>16</sup>O<sub>2</sub> (x), <sup>16</sup>,<sup>18</sup>O<sub>2</sub> (y), and <sup>18</sup>,<sup>18</sup>O<sub>2</sub> (z) originating from the Co(III)<sub>aq</sub> containing an atom fraction A = (0.5y + z)/(x + y + z) of <sup>18</sup>O are in isotopic equilibrium, *i.e.*, y<sup>2</sup>/xz = 4. Analogously the molar fractions <sup>16</sup>,<sup>16</sup>O<sub>2</sub> (k), <sup>16</sup>,<sup>18</sup>O<sub>2</sub> (l), and <sup>18</sup>,<sup>18</sup>O<sub>2</sub> (m) of oxygen originating from solvent contain an atom fraction B of <sup>18</sup>O (B = (0.5l + m)/(k + l + m) and l<sup>2</sup>/mk = 4). The oxygen formed is a mixture of molecules originating from the two sources and contains an atom fraction C of <sup>18</sup>O: C = (0.5y + 0.5l + z + m)/(x + y + z + k + l + m), and, as x + y + z + k + l + m = 1, C = 0.5(y + l) + z + m. If one defines the mole fraction of O<sub>2</sub> originating from the Co(III)<sub>aq</sub> as P = x + y + z, then C = AP + B(1 - P) or P = (C - B)/(A - B). From these equations one may derive that x = P(1 - A)<sup>2</sup>; y = 2AP(1 - A); z = PA<sup>2</sup>; k = (1 - P)(1 - B)<sup>2</sup>; l = 2B(1 - P)(1 - B); m = (1 - P)B<sup>2</sup>. Thus the values of the ratios α = <sup>16</sup>,<sup>16</sup>O<sub>2</sub>/<sup>16</sup>,<sup>18</sup>O<sub>2</sub> = (x + k)/(y + l) and β = <sup>18</sup>,<sup>18</sup>O<sub>2</sub>/<sup>16</sup>,<sup>18</sup>O<sub>2</sub> = (z + m)/(y + l) could be calculated on basis of the measured values of A, B, and C and

(12) F. Z. Roginsky, "Theoretical Principles of Isotope Methods for Investigating Chemical Reactions," Academy of Sciences, U.S.S.R. Press, Moscow, 1956.

ured with the ratios between the masses  $^{16,18}\text{O}_2$ ,  $^{16,18}\text{O}_2$  (34), and  $^{18,18}\text{O}_2$  (36) experimentally determined by the mass spectrometric analysis of the evolved  $\text{O}_2$  ( $f = (32)/(34)$  and  $g = (36)/(34)$ ). The results presented in Table I show a satisfactory agreement between calculated values of  $\alpha$  and  $\beta$  and the experimental values of  $f$  and  $g$ , respectively. Thus the assumption that the oxygen formed is a mixture of two types of molecules with practically no isotopic equilibrium between them has been verified. As the value of  $\alpha$  was much smaller than  $\beta$  and  $g$ , the accuracy of  $\alpha$  is smaller than that of  $f$ . Consequently the agreement between  $\alpha$  and  $f$  is evidently better than between  $\beta$  and  $g$ .

As the only explanation of these results we are able to give is the following. Oxygen is formed from binuclear complexes of  $\text{Co(III)}_{\text{aq}}$  and these oxygen molecules come exclusively from their inner hydration sphere. A  $\text{Co(III)}_{\text{aq}}$  solution (0.6 M in 6 M  $\text{HClO}_4$ ) contains 3.1% in percentage (<3.1%) of dimers having mostly the structure

in addition to monomeric  $\text{Co}(\text{H}_2\text{O})_6^{3+}$  ions. The formation of  $\text{O}_2$  from  $\text{Co(III)}_{\text{aq}}$  requires 4 equiv of  $\text{Co(III)}$ , which have to be in a dimeric form. Thus the presence of 6.2% of nonequilibrated oxygen implies the existence of  $\geq 3.1\%$  nonequilibrated dimers introduced into the dilute solution. If one assumes that the equilibrium  $\text{Co}(\text{H}_2\text{O})_6\text{OH}^{2+} \rightleftharpoons \text{dimer}$  is strongly shifted right, then the concentration of the dimer will be approximately equal to that of  $\text{Co}(\text{H}_2\text{O})_6\text{OH}^{2+}$ . The equilibrium constant for  $\text{Co}(\text{H}_2\text{O})_6^{3+} \rightleftharpoons \text{Co}(\text{H}_2\text{O})_5\text{OH}^{2+} + \text{H}^+$  has been found to be  $0.22 \pm 0.05$ .<sup>13</sup> With this value one may derive the concentration of dimers in 6 M  $\text{HClO}_4$  to be  $\leq 3.5\%$ , in good agreement with our findings. These dimers yield oxygen before undergoing isotopic exchange with the solvent. The monomeric  $\text{Co}(\text{H}_2\text{O})_6^{3+}$  has to undergo dimerization yielding  $\text{O}_2$ . However, the rate of water exchange of  $\text{Co}(\text{H}_2\text{O})_6^{3+}$  is faster than the rate of dimerization; thus the coordination sphere of the newly formed dimers, and consequently the  $\text{O}_2$  formed from them, will be in isotopic equilibrium with the solvent. The rate of the dimers present in the concentrated solution of  $\text{Co(III)}_{\text{aq}}$  undergo cleavage to give monomers, which will undergo complete isotopic exchange with the solvent before reacting to give a dimer again. The rapid exchange of the monomers is most probably induced by the  $\text{Co(II)}\text{--Co(III)}$  electron exchange.<sup>11</sup>

The existence of polynuclear species higher than dimers in our solution cannot be excluded. It is, however, unlikely that these exist in 6 M  $\text{HClO}_4$ , and their rate of formation is a rather slow process (cf. processes in  $\text{Fe(III)}$  or  $\text{Al(III)}$  solutions), their contribution to the over-all oxidation of water by  $\text{Co(III)}_{\text{aq}}$  under our experimental conditions may be neglected.

The mechanism of oxidation of the ligand in the dimeric  $\text{Co(III)}_{\text{aq}}$  remained an open question. Two alternative mechanisms are possible. (a) One is the intramolecular conversion of the dimeric complex of  $\text{Co(III)}$  into a binuclear peroxy complex of  $\text{Co(II)}$

active mechanisms are possible. (a) One is the intramolecular conversion of the dimeric complex of  $\text{Co(III)}$  into a binuclear peroxy complex of  $\text{Co(II)}$

followed by hydrolysis of the cobalto peroxide to  $\text{H}_2\text{O}_2 + 2\text{Co(II)}$ . The following steps would then be  $\text{H}_2\text{O}_2 + \text{Co}(\text{H}_2\text{O})_6^{3+} \rightarrow \text{Co}(\text{H}_2\text{O})_5\text{OH}^{2+} + \text{H}^+ + \text{HO}_2$  and  $\text{HO}_2 + \text{Co}(\text{H}_2\text{O})_6^{3+} \rightarrow \text{Co}(\text{H}_2\text{O})_5\text{OH}^{2+} + \text{O}_2 + \text{H}^+$ . (b) The other is an attack of  $\text{Co}(\text{H}_2\text{O})_6^{3+}$  on the dimeric aquo cobaltic complex

followed by the formation of  $\text{HO}_2$  radical

followed by either  $\text{HO}_2 + \text{Co}(\text{H}_2\text{O})_6^{3+} \rightarrow \text{O}_2 + \text{Co}(\text{H}_2\text{O})_6^{3+} + \text{H}^+$  or  $2\text{HO}_2 \rightarrow \text{H}_2\text{O}_2 + \text{O}_2$ .

As we know from the kinetic behavior of the  $\text{Co(III)}_{\text{aq}}$  oxidation of water, the rate of this reaction is proportional to  $[\text{H}_2\text{O}_2]^{1/2}$  which is implied in the pre-equilibrium:  $2\text{Co}(\text{H}_2\text{O})_6^{3+} \rightleftharpoons [(\text{H}_2\text{O})_4\text{CoOH}]^{++} + 2\text{H}^+$ .<sup>14</sup> As we have shown,  $\text{Co(III)}_{\text{aq}}$  dimers exist even in 6 M  $\text{HClO}_4$  solution; consequently, in less acid solution, e.g.,  $<0.01 \text{ N H}^+$ , practically all  $\text{Co(III)}_{\text{aq}}$  will be in the dimeric form.

In order to decide between the two mechanisms, we have carried out a series of experiments in which  $\text{Co(III)}_{\text{aq}}$  reacted with water in the presence of  $\text{H}_2\text{O}_2$ . We had to choose conditions where the rate of the  $\text{Co(III)}_{\text{aq}}\text{--H}_2\text{O}$  reaction competes with the  $\text{Co(III)}_{\text{aq}}\text{--H}_2\text{O}_2$  oxidation reaction. The kinetic information available for both reactions<sup>4</sup> indicates that only at low acidities and high dilutions of  $\text{Co(III)}_{\text{aq}}$  has the ligand oxidation a chance to compete with the  $\text{H}_2\text{O}_2$  reaction. Accordingly we chose pH 4 and  $[(\text{Co(III)}_{\text{aq}})] = 10^{-4} \text{ M}$  as the appropriate experimental conditions. Using  $\text{Co(III)}_{\text{aq}}$  and  $\text{H}_2\text{O}$  of different isotopic composition from that of  $\text{H}_2\text{O}_2$ , it was possible to examine by isotope dilution the amount of hydrogen peroxide formed as intermediate in the oxidation of water. The results presented in Table II show that under the experimental conditions some oxidation of water by  $\text{Co(III)}_{\text{aq}}$  took place in spite of the efficient competitive reaction of  $\text{Co(III)}_{\text{aq}}$  with  $\text{H}_2\text{O}_2$ ; moreover, some hydrogen peroxide produced from the  $\text{Co(III)}_{\text{aq}}$  and from water could be detected in the residual  $\text{H}_2\text{O}_2$ . From a quantitative evaluation of the results, one could determine

(14) An  $\text{OH}^-$  induced  $\text{S}_\text{N}2$  hydrolysis of the cobalto peroxide formed according to the first mechanism or of the complex formed by the second mechanism may be excluded in view of the measured rates and the steady-state concentration of  $\text{OH}^-$  ions in the range of acidities investigated.

**Table II.** The Isotopic Composition of Oxygen and Hydrogen Peroxide Formed from  $\text{Co(III)}_{\text{aq}}$  in the Presence of Hydrogen Peroxide\*

$\text{H}_2\text{O}$	$\text{Co(III)}_{\text{aq}}$	Atom % $^{18}\text{O}$ in	
		Evolved $\text{O}_2$	Residual $\text{H}_2\text{O}_2$
0.213	63.0	$1.71 \pm 0.30$	$0.402 \pm 0.03$
25.2	0.200	$0.54 \pm 0.06$	$0.311 \pm 0.04$
25.2	63.0	$2.48 \pm 0.42$	$0.432 \pm 0.04$

\*  $[\text{Co(III)}_{\text{aq}}] = 1.10^{-4} M$ ;  $[\text{H}_2\text{O}_2] = 2.10^{-4} M$ ;  $^{18}\text{O}$  content of  $\text{H}_2\text{O}_2 = 0.2$  atom %.

the mole fractions of  $\text{O}_2$  and  $\text{H}_2\text{O}_2$  which originate from the  $\text{Co(III)}_{\text{aq}}$  and from water, respectively.

As we have carried out these experiments with  $\text{Co(III)}_{\text{aq}}$  and  $\text{H}_2\text{O}$  of different isotopic composition (Table II), the contribution of each pathway could be determined by solving three simultaneous linear equations with three unknowns. From the composition of the evolved oxygen, it was calculated that under the experimental conditions  $2.3 \pm 0.4\%$  of the oxygen is formed from the  $\text{Co(III)}_{\text{aq}}$  (*i.e.*, from the dimers present in the original  $\text{Co(III)}_{\text{aq}}$  solution; see above), and  $1.4 \pm 0.3\%$  originates from the water. This means that in the presence of  $\text{H}_2\text{O}_2$  about 60% of the oxygen originates from the isotopically (nonequilibrated) dimers and only 40% from secondary dimers, compared with 16.2 *vs.* 93.2% in pure water. This result is not surprising if one assumes that the rate of reaction of  $\text{Co(H}_2\text{O)}_6^{3+}$  with  $\text{H}_2\text{O}_2$  is considerably faster than that of the  $\text{Co(III)}_{\text{aq}}$  dimer, which may undergo ligand oxidation before being reduced by  $\text{H}_2\text{O}_2$  in solution.

The analysis of the residual  $\text{H}_2\text{O}_2$  data shows that  $0.3 \pm 0.1\%$  of the  $\text{H}_2\text{O}_2$  originates from the  $\text{Co(III)}_{\text{aq}}$  and  $0.2 \pm 0.1\%$  from the water. The latter results indicate that  $\text{H}_2\text{O}_2$  is *not* the precursor of the oxygen evolved. If  $\text{H}_2\text{O}_2$  would be the only intermediate in the formation of  $\text{O}_2$  as required by mechanism a, one would expect to find much more  $\text{H}_2\text{O}_2$  originating from the  $\text{Co(III)}_{\text{aq}}-\text{H}_2\text{O}$  reaction in the residual  $\text{H}_2\text{O}_2$  than in the evolved oxygen. The small amounts of labeled  $\text{H}_2\text{O}_2$  detected are most probably due to the secondary reaction  $\text{HO}_2 + \text{HO}_2 \rightarrow \text{H}_2\text{O}_2 + \text{O}_2$ , which is unfavored in the presence of  $\text{H}_2\text{O}_2$  and of  $\text{Co(H}_2\text{O)}_6^{3+}$ .

Our results exclude the formation of an O—O bond in the dimer prior to its being attacked by  $\text{Co(H}_2\text{O)}_6^{3+}$ . If the cobaltic dimer would undergo spontaneous intramolecular conversion to a cobalto peroxide complex, the latter would undergo rapid hydrolysis, owing to the substitution lability of  $\text{Co(II)}$ , and release  $\text{H}_2\text{O}_2$ .

From the tracer experiment described here one may reach the following conclusions. (1)  $\text{O}_2$  is formed

from  $\text{Co(III)}_{\text{aq}}$  and water only *via* dimers. (2) The formation of oxygen involves the reaction of these dimers with  $\text{Co(H}_2\text{O)}_6^{3+}$  resulting in the formation of  $\text{HO}_2$  as intermediate. If the latter process is the rate-determining step, one would expect the rate at low acidity to be proportional to  $[\text{Co(III)}_{\text{aq}}]^{1/2}$ . Such a kinetic behavior has been actually observed,<sup>8</sup> and the results were interpreted by the same mechanism. We have thus corroborated the mechanism suggested by Baxendale and Wells which has been challenged<sup>4</sup> for lack of supporting evidence. (3)  $\text{Co(III)}_{\text{aq}}$  contains substantial amounts of dimers even in concentrated acid solutions. In less acid solution  $\text{Co(III)}_{\text{aq}}$  is predominantly in the dimeric form.

The formation of dimeric aquo or hydroxo complexes of  $\text{Co(III)}$  should not be surprising in view of the existence of other binuclear  $\text{Co(III)}$  complexes such as<sup>15,16</sup>

or of analogous  $\text{Cr(III)}$  binuclear complexes<sup>17</sup>

It is interesting to note that the oxidation of substituted  $\text{Co(II)}$  complexes, *e.g.*,  $[\text{Co}(\text{NH}_3)_5\text{H}_2\text{O}]^{2+}$ <sup>18</sup> or  $[\text{Co}(\text{CN})_5\text{H}_2\text{O}]^{2-}$ ,<sup>19</sup> by molecular oxygen produces binuclear peroxy complexes of the type  $[(\text{NC})_5\text{Co}(\text{O}_2)\text{Co}(\text{CN})_5]^{6-}$  or  $[(\text{NH}_3)_5\text{Co}(\text{O}_2)\text{Co}(\text{NH}_3)_5]^{4+}$ , which may be further oxidized to  $[(\text{NC})_5\text{Co}(\text{O}_2)\text{Co}(\text{CN})_5]^{5-}$  and  $[(\text{NH}_3)_5\text{Co}(\text{O}_2)\text{Co}(\text{NH}_3)_5]^{3+}$ , respectively.<sup>20</sup> These complexes are most probably closely related with the intermediate postulated in this study.

# Formation of Open-Cage and Closed-Cage Carboranes from Tetraborane(10) and Acetylene

Russell N. Grimes and Christopher L. Bramlett<sup>1</sup>

Contribution from the Cobb Chemical Laboratory, University of Virginia, Charlottesville, Virginia. Received December 22, 1966

**Abstract:** The vapor-phase reaction of tetraborane(10) and acetylene has been examined at 25, 50, and 100°, and the volatile products were isolated and structurally characterized. At 25 and 50°, methyl derivatives of tricarbaheptaborane(7) and monocarbaheptaborane(9) are formed. At 100° a flash reaction takes place in which nine volatile products are obtained, all of which are closed-cage carboranes having three to eight boron atoms. Pyrolysis of the 2-methyl and 2,4-dimethyl derivatives of 2,3,4-tricarbaheptaborane(7) yields no carboranes, but the 2,3-dimethyl derivative produces new dimethyl derivatives of 2,4-dicarbaloheptaborane(7) and tricarbaheptaborane(7) in small yields. Comparison of these results with earlier work from several laboratories permits some tentative conclusions concerning carborane formation in vapor-phase alkyne-borane reactions.

In recent years a number of carborane cage compounds have been synthesized by direct reactions of saturated hydrocarbons with boranes in the vapor phase.

Several observations concerning these reactions now seem to have general significance: (1) simple alkynes often lead to carborane formation, but do not; (2) formation of closed-cage species ( $B_nH_{n+2}$  series) is favored in high-energy situations such as electric discharges<sup>2-4</sup> or flash reactions;<sup>5,6</sup> (3) synthesis of open-cage carboranes containing hydrocarbon bridges, e.g.,  $CB_5H_8$ ,<sup>7</sup>  $C_2B_4H_8$ ,<sup>8</sup>  $C_3B_3H_7$ ,<sup>9</sup> or derivatives of these, occurs under comparatively mild conditions (thermally induced reactions at 25 to 100°); (4) formation of methyl-substituted carboranes from acetylene is common in both high-energy and low-energy reactions;<sup>2-7,9</sup> (5) methyl substitution occurs predominantly in boron cage positions in the high-energy syntheses, but C-methylation is frequently observed in low-energy reactions.

Previous reports of carborane formation from reactions in the vapor phase have involved  $B_2H_6$ ,<sup>5,6</sup>  $B_4H_{10}$ ,<sup>4,7,8</sup> or  $B_6H_{12}$ <sup>10</sup> as reactants. The action of acetylene on ethylene has been studied,<sup>11,12</sup> but no carboranes are produced and the principal product is 2,4-diylenetetraborane. In this paper we describe an investigation of the vapor-phase interaction between acetylene and tetraborane in which both open- and closed-cage carboranes were obtained under varying conditions.

The results of this study lend further support

to the above generalizations and offer some insight into the nature of the carborane-forming processes in these systems.

## Results and Discussion

**Reactions at 25 and 50°.** The gas-phase reaction between chromatographically pure  $B_4H_{10}$  and  $C_2H_2$  in a 1:1 mole ratio takes place slowly at room temperature, and more rapidly at 50°, to give a white, non-volatile organoboron polymer and several volatile carboranes, all having open-cage structures (Table I). In addition to  $B_4H_{10}$  and an unstable material which may be the parent 2,3,4-tricarbaheptaborane(7), the products are the 2-methyl, 2,3-dimethyl, and 2,4-dimethyl derivatives of 2,3,4-tricarbaheptaborane(7), the infrared spectra of which are presented in Table II, plus 4-methyl-2-carbaheptaborane(9). (The last-mentioned compound has been previously reported<sup>7</sup> as a product of the reaction of  $B_4H_{10}$  with  $C_2H_2$  at 215°.) No other volatile materials have been detected in significant amounts despite the use of sensitive chromatographic methods, and the same products were obtained at 50° as at 25°.

The white solid is highly reactive toward both dry air, in which it inflames, and moisture, which rapidly degrades it to boric acid. Infrared analysis indicates the presence of both CH and  $BH_2$  groups and strongly suggests a polymeric structure. The formation of this material is not wall catalyzed, since it is produced homogeneously throughout the reactor and settles to the bottom, and it appears to be the major product of a gas-phase hydroboration attack of acetylene on  $B_4H_{10}$  in which the volatile carboranes are side products.

These results for the  $B_4H_{10}$ - $C_2H_2$  system are in sharp contrast to those recently reported for the  $B_2H_6$ - $C_2H_2$  gas-phase reaction,<sup>14</sup> in which ethyldiborane and 1,1-diethyldiborane were the major volatile products at 85° and no carboranes were found. Thus it is clear that none of the carborane products obtained in the present work could have resulted from direct interactions between  $C_2H_2$  and  $B_2H_6$  (some of which is always present as a decomposition product in  $B_4H_{10}$  vapor). Moreover, since other experiments<sup>15</sup> have established that neither  $B_4H_{10}$  nor  $B_6H_{12}$  combines with  $C_2H_2$  at room

Philip Francis du Pont Predoctoral Fellow, 1965-1967.

Although both open- and closed-cage carboranes have been prepared by other methods, we wish to restrict this discussion to direct reactions between hydrocarbons and boranes.

<sup>a</sup> In  $cm^{-1}$  at 25 mm pressure.

temperature to give more than traces of the tricarbahehexaborane(7) products in Table I, it is apparent that the two pentaboranes, as such, are not significant intermediates in the formation of the  $C_2B_2H_7$  derivatives from  $B_4H_{10}$ . We conclude, then, that formation of the  $C_2B_2H_7$  products is initiated by a direct attack of  $C_2H_2$  on  $B_4H_{10}$  itself or on a fragment formed therefrom ( $B_3H_7$  is a reasonable possibility).

**Reaction at 100°.** The interaction between  $B_4H_{10}$  and  $C_2H_2$  at 100° is of an entirely different nature from that occurring at 25 or 50°. Within a few minutes an equimolar mixture flashes, yielding dark gray solids and a series of nine volatile closed-cage carboranes having no hydrogen bridges (Table I). With the exception of 2- $CH_2C_2B_2H_6$ ,  $C_2B_2H_{10}$ , and B- $CH_2C_2B_2H_6$ , the same species have also been produced in electric discharges of  $B_2H_6$ - $C_2H_2$  mixtures,<sup>6</sup> which implies somewhat similar mechanisms. It is notable, however, that among the products obtained in the present study there is no indication of the 1,2- $C_2B_2H_6$  methyl derivatives<sup>5,6,16</sup>

(16) R. N. Grimes, *J. Organometal. Chem.* (Amsterdam), in press.

which were significant products of the  $B_2H_6$ - $C_2H_2$  discharge reaction.

**Pyrolysis of Tricarbahehexaborane(7) Derivatives.** In order to examine the possibility that the alkylated  $C_2B_2H_7$  species which form at low temperatures might be intermediates in the synthesis of closed-cage carboranes at 100°, vapor-phase pyrolysis experiments have been carried out on the three  $C_2B_2H_7$  methyl derivatives obtained in the  $B_4H_{10}$ - $C_2H_2$  reaction at 25°. All three compounds are completely stable at 100°, and neither 2- $CH_2C_2B_2H_6$  nor 2,4-( $CH_3$ ) $_2C_2B_2H_6$  is affected by heating at 250° for several days, although the latter substance decomposes at 350° to hydrogen and nonvolatile solids. The 2,3-dimethyl derivative, on the other hand, at 250° gives traces of a dimethyl-2,4-dicarbaheheptaborane(7) plus a B,C-dimethyl derivative of  $C_2B_2H_7$ , and at 300° yields a small quantity of a second ( $CH_3$ ) $_2C_2B_2H_6$  product which appears to be alkylated at the B(1) and B(7) positions.

Clearly the  $C_2B_2H_7$  derivatives are not significant precursors of the closed-cage molecules which form in the 100° reaction.<sup>17</sup> Indeed it is not surprising that the  $C_2B_2H_7$  cage system appears to have far less tendency to form closed-cage carboranes on pyrolysis than does the structurally similar (and isoelectronic)  $C_2B_4H_6$ .<sup>8,18</sup> This is to be expected from the accepted valence theory for the polyhedral carboranes, which requires two cage carbon atoms and therefore necessitates the formal "ejection" of one carbon from the  $C_2B_2H_7$  framework before closure can be completed.

While a detailed clarification of the reaction mechanisms involved in acetylene-borane interactions is not yet available, a comparison of the results of this work with those from earlier investigations does permit some tentative observations. First, it is now evident that, in the low-energy reactions, the nature of the products obtained is strongly dependent on the specific borane starting material. As the data in Table III indicate, the four boranes whose gas-phase reactions with acetylene have been studied under moderate conditions give almost totally different sets of products.<sup>18a</sup> This is certainly reasonable from the viewpoint that the experimental conditions in each case do not presage extensive

(17) The possibility of interaction between the  $C_2B_2H_7$  derivatives and  $C_2H_2$  was eliminated by appropriate control experiments in which no reaction was observed.

(18) T. P. Onak, F. J. Gerhart, and R. E. Williams, *J. Am. Chem. Soc.*, **85**, 3378 (1963).

(18a) NOTE ADDED IN PROOF. Results obtained in this laboratory on the  $B_4H_{10}$ - $C_2H_2$  system fit the pattern indicated in Tables III and IV. At 25° the major product is 2- $C_2H_5B_2H_6$ , while the 100° flash reaction virtually duplicates the results of the 100°  $B_4H_{10}$ - $C_2H_2$  reaction.

integration of the borane framework, and the organo- on products evidently retain many of the B-H /or B-B bonds present in the borane reactant.

In considering the rapid, high-energy interactions between acetylene and boranes, however, one is led to a different conclusion. Although some variation in product mixtures is evident in the three systems that have been studied (Table IV), *all* of the volatile organoboron products so far identified in these reactions are closed-cage carboranes. It should be noted further that in cage systems,  $1,6\text{-C}_2\text{B}_4\text{H}_6$  and  $2,4\text{-C}_2\text{B}_5\text{H}_7$ , are predominant in each case. At least insofar as these three reaction systems are concerned, it is apparent that the specific cage structure of the borane reactant is not a major factor in determining final product structures, that mechanisms involving severe disruption of the borane framework must be dominant. In this situation it may be assumed that the final product distribution is largely determined by the relative thermodynamic stabilities of the carborane cage systems.

\* Vapor phase.

In summary, it is reasonable to expect that still unknown high-energy vapor-phase interactions between boranes and acetylene will yield a series of closed-cage carboranes and derivatives similar to those in Table IV. As a consequence, the remaining undiscovered borane systems will most probably be synthesized under relatively mild, controlled reaction conditions which favor at least partial retention of the original

borane cage structure and which limit the extent of cage rearrangement in the products.

## Experimental Section

**Materials.**  $\text{B}_2\text{H}_{10}$  was prepared from  $\text{B}_2\text{H}_6$  (Olin Mathieson) by the hot-cold reactor method of Klein, *et al.*,<sup>19</sup> and was purified by repeated fractionation through traps at  $-95$  and  $-135^\circ$ ; the purity was monitored by gas chromatography and infrared spectra.  $\text{C}_2\text{H}_2$  (Matheson) was purified by passage through a  $-135^\circ$  trap several times and was checked by infrared analysis.

**Procedures.** All reactions were carried out in sealed Pyrex bulbs equipped with break-off tips. Volatile products were separated by preparative-scale gas chromatography under air-free conditions using either a  $9.5\text{ ft} \times 0.25\text{ in.}$  column of tricresyl phosphate on Chromosorb W or a  $9.5\text{ ft} \times 0.25\text{ in.}$  column of Kel-F on Chromosorb W. Purification of individual products was effected by repeated passages through the column when necessary.

**Spectroscopy.** Infrared spectra were obtained on a Beckman IR-8 grating spectrophotometer. Gas infrared spectra were measured in a  $3.5\text{-ml}$ ,  $9\text{-cm}$  Pyrex cell with NaCl windows. Mass spectra were recorded on a CEC 21-103C spectrometer with digital readout, proton nmr spectra were obtained on a Varian A-60 instrument, and  $^{11}\text{B}$  nmr spectra were measured with a Varian HR-100 spectrometer at  $32.2\text{ Mc}$ .

**Reactions of Tetraborane(10) with Acetylene.** Measured quantities of tetraborane(10) and acetylene were condensed into an evacuated  $125\text{- or }500\text{-ml}$  flask cooled in liquid nitrogen, after which the reactor was sealed and the reaction allowed to proceed to the desired temperature (Table I). At  $25^\circ$ , reaction was evidenced after 1 to 2 hr by the accumulation of a white solid at the bottom. At  $50^\circ$  the same effect was noted within 2 to 3 min. In the experiments at  $100^\circ$ , typically within 6 min a flash was observed with instantaneous formation of large quantities of dark solids, which were not investigated. No breakage of the reactor was observed when the  $\text{C}_2\text{H}_2\text{:B}_4\text{H}_{10}$  ratio was 1.0 or less, but when a 2:1 ratio was used the result was a violent explosion (Table I).

Following each experiment most of the unreacted  $\text{B}_4\text{H}_{10}$  and  $\text{C}_2\text{H}_2$  was removed by passage through a trap at  $-95^\circ$ , after which the volatile products were separated by chromatography as described above.  $2\text{-CH}_3\text{C}_2\text{B}_2\text{H}_5$ ,  $2,3\text{-(CH}_3)_2\text{C}_2\text{B}_2\text{H}_4$ , and  $2,4\text{-(CH}_3)_2\text{C}_2\text{B}_2\text{H}_4$  were structurally characterized by means of their  $^1\text{H}$  and  $^{11}\text{B}$  nmr, infrared, and mass spectra as reported earlier.<sup>9</sup> An additional product which has an infrared spectrum similar to the three  $\text{C}_2\text{B}_2\text{H}_4$  derivatives, except for the bands attributable to methyl groups, is possibly the parent  $\text{C}_2\text{B}_2\text{H}_4$ , but further investigation of this material was hampered by its instability even at room temperature.  $4\text{-CH}_3\text{CB}_2\text{H}_5$  was identified from its mass spectrum, which is in precise agreement with the published spectrum<sup>7</sup> and is clearly distinguishable from the other known carborane fragmentation patterns.

Several attempts to remove the white polymer from the reactor in order to obtain an infrared spectrum were unsuccessful, even in dry argon, due to reaction with traces of oxygen or moisture. This problem was finally circumvented by allowing the reaction between  $\text{B}_4\text{H}_{10}$  and  $\text{C}_2\text{H}_2$  to proceed in a gas infrared cell in such a manner that the solid collected on the NaCl windows. All volatile materials were then removed, and the spectrum of the solid was recorded. The only well-defined bands are at  $2900$  and  $2500\text{ cm}^{-1}$ , but a series of broad absorptions appears between  $700$  and  $1500\text{ cm}^{-1}$ . The spectrum was unchanged after the cell had stood 13 days at room temperature.

Of the products obtained in the  $100^\circ$  flash reaction, the following were identified by comparison of their infrared and mass spectra<sup>4-6</sup> with those of authentic samples:  $2\text{-CH}_3\text{-1,5-C}_2\text{B}_4\text{H}_6$ ,  $1,6\text{-C}_2\text{B}_4\text{H}_6$ ,  $2,4\text{-C}_2\text{B}_5\text{H}_7$ ,  $1\text{-CH}_3\text{-2,4-C}_2\text{B}_5\text{H}_7$ ,  $3\text{-CH}_3\text{-2,4-C}_2\text{B}_5\text{H}_7$ , and  $5\text{-CH}_3\text{-2,4-C}_2\text{B}_5\text{H}_7$ .  $2\text{-CH}_3\text{-2,4-C}_2\text{B}_5\text{H}_7$ , which is the only other possible monomethyl derivative<sup>20</sup> of  $2,4\text{-C}_2\text{B}_5\text{H}_7$ , was characterized from its mass spectrum (high-mass cutoff =  $m/e\ 100$ , and the calculated boron-11 monoisotopic fragmentation pattern closely resembles the patterns of known  $\text{C}_2\text{B}_5\text{H}_7$  derivatives) and its infrared absorption bands, which appear at  $2925$  (s),  $2870$  (m),  $2590$  (vs),  $1440$  (m, b),  $1195$  (s),  $1110$  (m),  $1025$  (m),  $955$  (w),  $890$  (w),  $850$  (w),  $780$  (w), and  $710$  (m)  $\text{cm}^{-1}$ . Absence of bridge hydrogens is indicated by the lack of absorptions between  $1500$  and  $2500\text{ cm}^{-1}$ . The existence of a band at  $1440\text{ cm}^{-1}$ , while none is found near  $1320\text{ cm}^{-1}$ ,

(19) M. J. Klein, B. C. Harrison, and I. Solomon, *J. Am. Chem. Soc.*, **80**, 4149 (1958).

(20) Excluding optical isomers.

is indicative of a C-methyl rather than a B-methyl group, and the spectrum in the cage vibrational region (700 to 1200  $\text{cm}^{-1}$ ) is similar to the spectra<sup>4</sup> of 2,4- $\text{C}_2\text{B}_2\text{H}_7$  and its derivatives.

Identification of  $\text{C}_2\text{B}_2\text{H}_{10}$  was accomplished from its mass spectrum (high-mass cutoff =  $m/e$  122, and the fragmentation pattern is characteristic of a closed-cage carborane<sup>11</sup>) and the infrared spectrum, which discloses no alkyl substituents or bridge hydrogens. Bands are observed at 3090 (w), 2590 (vs), 1310 (w, b), 1125 (s), 1110 (sh), 1040 (w), 970 (m), 960 (m), 945 (m), 880 (m), 815 (m), 775 (s), and 660 (s)  $\text{cm}^{-1}$ . Since the spectrum of authentic  $\text{C}_2\text{C}'\text{-(CH}_3)_2\text{-1,6-C}_2\text{B}_2\text{H}_8$  is similar in the cage vibrational region, while that of  $\text{C}_2\text{C}'\text{-(CH}_3)_2\text{-1,10-C}_2\text{B}_2\text{H}_8$  is quite different,<sup>12</sup> it seems likely that the  $\text{C}_2\text{B}_2\text{H}_{10}$  product described here is the 1,6 isomer.

Characterization of the B-methyl derivative of  $\text{C}_2\text{B}_2\text{H}_{10}$  was similarly based on infrared and mass spectra. The high-mass cutoff is at  $m/e$  136, and the fragmentation pattern is very close to that of the  $\text{C}_2\text{B}_2\text{H}_{10}$  described above. The infrared bands are at 2940 (w), 2585 (vs), 1315 (s), 1170 (m), 1130 (s), 1090 (w), 1030 (w, b), 970 (w, b), and 670 (m)  $\text{cm}^{-1}$ . B-Methyl deformation is indicated by the characteristic band at 1315  $\text{cm}^{-1}$  and the absence of a significant absorption near 1450  $\text{cm}^{-1}$  (C-CH<sub>3</sub> deformations).

**Pyrolysis of Tricarbahexaborane(7) Derivatives.** 2- $\text{CH}_3\text{C}_2\text{B}_2\text{H}_8$  (0.03 mmole) was sealed in a 7-ml reactor and heated 5 days at 250°, at the end of which all of the starting material was recovered unchanged. Similarly, 2,4- $(\text{CH}_3)_2\text{C}_2\text{B}_2\text{H}_8$  (0.01 mmole) in a 15-ml tube did not react in 16 hr at 250°. The same sample was replaced in the reactor and heated 19 hr at 350°, after which only nonvolatile solids and H<sub>2</sub> remained.

(21) A compact, stable framework which resists breakdown is indicated by the fact that the peaks in the parent group (fragments formed by loss of H only) are the most intense in the spectrum; see ref 3, 4, 7, and 16.

(22) The spectra of the dimethyl derivatives of  $\text{C}_2\text{B}_2\text{H}_{10}$  were provided by Professor M. F. Hawthorne, University of California, Riverside, Calif.

2,3- $(\text{CH}_3)_2\text{C}_2\text{B}_2\text{H}_8$  (0.100 mmole) in a 10-ml tube failed to react at 100° over a 20-hr period. The same sample in 120 hr at 250° gave cleanly, with no solids, 0.016 mmole of a dimethyl derivative of 2,4- $\text{C}_2\text{B}_2\text{H}_7$ . The mass spectrum of this compound has a high-mass cutoff at  $m/e$  114, and the calculated boron-11 monoisotopic spectrum is characteristic of the 2,4- $\text{C}_2\text{B}_2\text{H}_7$  cage structure. The infrared spectrum has bands indicating C-H, B-H, C-CH<sub>3</sub>, and B-CH<sub>3</sub> groups, and the cage vibrational bands are similar to those of known 2,4- $\text{C}_2\text{B}_2\text{H}_7$  derivatives.<sup>4</sup> Also obtained in the same pyrolysis was 0.012 mmole of a product characterized as a B,C-dimethyl derivative of 2,3,4- $\text{C}_2\text{B}_2\text{H}_7$ . The mass spectrum has a high-mass cutoff at  $m/e$  104 and the fragmentation pattern closely matches those of the known derivatives of  $\text{C}_2\text{B}_2\text{H}_7$ .<sup>6</sup> Moreover, calculated boron-11 monoisotopic spectra can be fitted to the observed data only when three borons or fewer are assumed. The infrared spectrum contains, in addition to C-H, B-H, and bridge proton bands, absorptions at 1450 and 1320  $\text{cm}^{-1}$  which are characteristic of C-CH<sub>3</sub> and B-CH<sub>3</sub> deformations, respectively.

The same starting material (2,3- $(\text{CH}_3)_2\text{C}_2\text{B}_2\text{H}_8$ , 0.045 mmole) was heated to 300° for 7 days, after which chromatographic and infrared analyses disclosed the same two products as were obtained at 250° (see above), plus an additional product which is probably 1,7- $(\text{CH}_3)_2\text{-2,4-C}_2\text{B}_2\text{H}_8$ . Identification was by means of the mass spectrum (high-mass cutoff at  $m/e$  114) and the infrared spectrum, which contains no C-CH<sub>3</sub> deformation bands but has a very strong absorption at 1320  $\text{cm}^{-1}$ , the B-CH<sub>3</sub> deformation frequency. In addition, the cage vibrational region is remarkably similar to that in 1- $\text{CH}_3\text{-2,4-C}_2\text{B}_2\text{H}_8$  (the monoapically substituted derivative),<sup>6</sup> which is taken as a strong indication that this product is the 1,7 (diapically substituted) derivative.

Received October 31, 1966

**Abstract:** A scheme is presented summarizing the structural and mechanistic relationships among the nine methylnorbornyl cations. References are given to the accompanying papers which detail experimental evidence supporting the scheme.

In accompanying papers<sup>4-8</sup> we report the results of several investigations of the behavior of carbocations of the norbornyl series labeled with methyl. These studies supplement extensive previous work on norbornyl cations<sup>9</sup> and, in particular, permit discussion of several aspects of the chemistry of these cations not readily visible heretofore. These include: relative rates of vicinal *vs.* transannular hydride shifts, the relative rates of hydride shift and capvolvement, the stereochemistry of vicinal hydride shifts, and the quantitative evaluation of transition-state effects in solvolysis and product formation. These studies bear on the vexatious question of the precise nature (classical *vs.* nonclassical) of the structure of the intermediates and provide experimental evidence that the "windshield-wiper effect" cannot be observed in all of their special stereochemical behavior<sup>9</sup>.

Scheme I is intended as a guide to the complex maze of structural and mechanistic relationships embodied in the work. In the papers that follow, experimental evidence is presented in support of the various parts of the scheme.

Reversions of nine different Wagner-Meerwein rearrangements are involved in Scheme I. The pairs are shown in full below but for economy of space are shown in Scheme I in nonclassical notation without implication as to the electronic structure. (Mechanistically,

Scheme I

ten cations should be considered, but the B<sub>1</sub>-B<sub>2</sub> set is structurally and stereochemically degenerate.) At the core of the scheme are the parent cations A, B, and C, which are mutually interconvertible by transannular "6,2"-hydride shifts. On the periphery lies another set of 6,2-hydride shifts which in principle might interconvert six pairs of cations. Access from the core to the periphery (or *vice versa*) is by way of vicinal "3,2"-hydride and/or methyl shifts, which interconvert either a pair of secondary cations (light arrows) or a tertiary with a secondary cation (heavy arrows). The scheme is oversimplified in the sense that additional intermediates describing ion-pair return processes should be included. Although it seems entirely probable that such processes do occur, their influence on the product patterns does not seem to be significant (papers IV, V, and VI<sup>4-6</sup>).

The cyclic series of rearrangements can be entered *via* solvolyses of several methyl-substituted norbornyl derivatives. The location of the methyl group relative to the positive charge at C-2 in the resulting first intermediate is 3-*endo*:7-*anti* (cation A, paper V<sup>7</sup>), 3-*exo*:7-*syn* (cation C, paper VI<sup>8</sup>), 5-*exo*:5-*endo* (cation B, paper IV<sup>6</sup>), and 6-*exo*:6-*endo* (cation B<sub>1</sub> = B<sub>2</sub>, paper IV<sup>6</sup>). Under kinetically controlled conditions, the six products from the inner core set of cations A, B, and C are observed regardless of which entry into the cycle

is used. The influence of solvent and point of entry on the distribution of these products gives some information on relative rates of hydride shift and nucleophilic capture. The steric effect of a methyl group in

various positions of the norbornyl system also is elucidated from the product distributions (paper IV<sup>6</sup>). Three additional products, 1, 2, and 3, are observed. These are derived from the vicinal *exo*-hydride shift which

converts secondary cation A to tertiary cation A<sub>1</sub>. Vicinal hydride and/or methyl shift which interconverts two secondary ions (B → B<sub>1</sub>, C → C<sub>1</sub>, A → A<sub>2</sub>) is slow. Even the stability associated with tertiary cation A<sub>1</sub> is insufficient to force vicinal hydride shift (D → A<sub>1</sub>) when the migrating hydrogen departs from a secondary center (papers IV and V<sup>6,7</sup>). Direct vicinal shift of an *endo*-hydride, even when tertiary-secondary (C → C<sub>2</sub>), does not occur (blocked heavy arrow of Scheme I). Thus, entry into the core cycle at cation C eventually does give products 1, 2, and 3 derived from a tertiary cation, *but only by a circuitous route*. This involves conversion of C to A followed by exit *via* cation A<sub>1</sub>, the enantiomer of C<sub>2</sub>. The distinction is made on the basis of stereochemical correlations given in papers III,<sup>5</sup> V,<sup>7</sup> and VI.<sup>8</sup>

The preference for *exo*-3,2-hydride shift is not attributable to a large thermodynamic bias favoring cation A over cation C but rather to an intrinsically faster rate for *exo* than for *endo* migration (paper VI<sup>8</sup>). This behavior is consistent with the formulation of the cationic intermediates with nonclassical structures.

# The Chemistry of Methylnorbornyl Cations. II. Sources and Identification of Sixteen of the Methylnorbornanols<sup>1</sup>

Jerome A. Berson,<sup>2a,b</sup> Arthur W. McRowe,<sup>2b</sup> Robert G. Bergman,<sup>2b,3</sup> and Donald Houston<sup>2c</sup>

Contribution from the Departments of Chemistry, University of Wisconsin, Madison, Wisconsin, and the University of Southern California, Los Angeles, California. Received October 31, 1966

**Abstract:** Structures are assigned to 16 of the methylnorbornanols by a variety of methods including independent syntheses, structural interconversions, and proton magnetic resonance spectroscopy. The substances involved are the four 3-methyl-2-norbornanols, the four 5- and 6-methyl-2-*exo*-norbornanols, the two 7-methyl-2-*exo*-norbornanols, the two 1-methyl-2-norbornanols, the two 1-methyl-3-norbornanols, and the two 2-methyl-2-norbornanols.

In connection with studies of methyl-labeled norbornyl cations,<sup>4</sup> it was necessary to be able to identify the methylnorbornanols. Since some of these compounds were unknown when this work was begun, the literature did not provide strong assignments of structure or unambiguous methods of synthesis for the others, we set out to acquire the needed information. This paper presents the results.

**Four 3-Methyl-2-norbornanols.** Both of the previously known stereoisomers of 3-methyl-2-norbornanol, **2a**, have an *endo* hydroxyl and differ only in the position of the methyl group. The configurations assigned<sup>4,6</sup> on the following grounds. The *cis-endo* isomer **2a** and the 3-*exo*-methyl isomer **1a** were the products of the lithium aluminum hydride reduction of 3-*endo*- and 3-*exo*-methyl-2-norbornanone (**3** and **4**, respectively).<sup>6</sup> We confirm this in the case of ketone **4** which gives 86.6% **1a** and 13.4% *cis-exo* isomer (**10**).<sup>4,6</sup> In other examples of such reactions with unsubstituted norbornanones<sup>7</sup> suggested that

attack from the *exo* direction would be preferred. Further, of the two alcohols then known, the one derived from **4** showed the larger cryoscopic molecular weight exaltation and was thus the less hindered, as would be expected for the *trans* member of a *cis-trans-endo* pair.<sup>5,6</sup>

Syntheses of the two remaining members of the series provide confirmation of the assignments. The other *trans* isomer **5** is obtained by two routes, first by the "acid  $\rightarrow$  acetate" sequence from the known<sup>8,9a</sup> 3-*endo*-methyl-2-*exo*-norbornanecarboxylic acid (**6a**), and also by hydroboration-oxidation<sup>8b</sup> of 2-methyl-2-norbornene (**9**).<sup>9</sup> The second procedure is more easily

adapted to the preparation of substantial quantities of alcohol **5**, since the requisite olefin **9** is readily available, and the hydroboration-oxidation step, in accord with previous experience,<sup>8b</sup> proceeds quite cleanly in an *exo-cis* anti-Markovnikov manner. The crude product is 94% **5** and is readily purified to the level of 99% or better by a single pass through an automatic preparative gas chromatograph.

The *cis-exo* acetate **10** is obtained as a side product in the Baeyer-Villiger oxidation of 3-*exo*-methyl-2-*endo*-acetylnorbornane (**11**), which in turn is preparable

from the known<sup>6</sup> 3-*exo*-methyl-2-*endo*-carboxylic acid (12). Oxidation with perbenzoic acid is slow, but no epimerization occurs, and 3-*exo*-methyl-2-*endo*-norbornyl acetate (1b) is obtained free of 10. Although oxidation with peroxytrifluoroacetic acid is faster, epimerization now becomes noticeable, and isolable quantities of the *cis*-*exo* acetate 10 are formed. This substance is also the minor component of the mixture obtained by acetylation of the lithium aluminum hydride reduction product from 3-*exo*-methyl-2-norbornanone (4).

The configurational assignments are confirmed by the nuclear magnetic resonance (nmr) spectra. In the acetates, the C-2 proton resonance occurs in a readily identifiable region about 4.5 ppm downfield from tetramethylsilane. The spectrum of the *cis*-*endo* acetate 2a shows this resonance as a doublet of doublets with  $J \cong 5$ , 4 cps; that of the *cis*-*exo* acetate 10 shows a broadened doublet,  $J = 7$  cps. The pattern in the 2a spectrum is consistent with moderately strong coupling between the C-2 proton and both the C-3 and C-1 protons, as has been observed with many other C-2 *exo* protons in analogous systems.<sup>10</sup> In 10, however, the C-2 *endo* proton is strongly coupled only to the *cis*-*endo* proton at C-3 and weakly or not at all to the bridgehead C-1 proton, again in accord with experience.<sup>10</sup> Although we have made no real attempt to identify it, the additional weak coupling that produces the slight broadening of the components of the C-2 multiplet (3.5 cps width at half-height) probably is attributable to long-range splitting, perhaps with the *anti*-7 proton.<sup>10</sup> This interpretation is supported by the absence of such broadening in 7-*anti*-methyl-2-*exo*-norbornyl acetate, the C-2 spectrum of which shows a doublet of doublets with widths at half-height of <1 cps for each component. The spectrum of the *trans* compound 1a, with a C-2 *exo* proton, shows a doublet of doublets,  $J \cong 3.5$ , 3.5 cps. These splittings are about the same as those previously observed for C-1 to *exo* C-2 and *trans* C-2 to C-3 couplings,<sup>10</sup> in agreement with the assigned stereochemistry. In the spectrum of *trans*-acetate 8, with a C-2 *endo* proton, one sees a poorly resolved doublet of doublets, in accord with the expected relatively weak long-range and *trans*-vicinal couplings.<sup>10</sup>

**The 5- and 6-Methyl-2-*exo*-norbornanols.** Esters of an alcohol assigned the structure 5-*exo*-methyl-2-*exo*-norbornanol (13) were isolated from formic acid or acetic-sulfuric acid treatment of a hydrocarbon assigned the structure 5-*endo*-methylnorbornene (14)<sup>11</sup> and from formolysis of *syn*-7-methyl-2-*exo*-norbornyl acid phthalate (15).<sup>12</sup> Oxidation of 13 and 14 gave two different 4-methylcyclopentane-*cis*-1,3-dicarboxylic acids.<sup>12</sup> The possibility that the alcohol was a 6-methyl derivative was excluded on the grounds that its formation from 15 would require a vicinal secondary-secondary hydride shift, which had been sought for and not found in the parent norbornyl system.<sup>13</sup> The *exo* configuration for the hydroxyl group was assigned<sup>12</sup> on the basis of the observed facile further rearrangement of the alcohol in formic acid. These arguments,

while plausible, are not completely convincing. The exclusion of the 6-methyl possibility seems less than absolute, since it now is quite probable<sup>14</sup> that vicinal secondary-secondary shift, although slow, does occur in formic acid, especially under equilibrating conditions. The assignment of the *exo* stereochemistry to the methyl group of 13 depends critically on the assignment of the *endo* stereochemistry to the hydrocarbon 14. Otherwise, the argument is circular, for internally, the oxidation-hydration scheme merely demonstrates that the alkene and the alcohol are Wagner-Meerwein related and would apply equally well to the *exo*-methyl-norbornene-*endo*-methyl alcohol pair. The assignment of stereochemistry to the hydrocarbon 14 rests entirely on the application of the Alder rule of *endo* addition to the precursors (the cyclopentadiene adducts 16 and 17) used for its preparation.<sup>11</sup> Since the rule is frequently violated,<sup>15</sup> independent evidence for the assignments of stereochemistry seems desirable.

Stereochemically homogeneous *endo*- and *exo*-2-methyl-5-norbornenes (14 and 18) can be prepared from the corresponding known<sup>16,17a</sup> carboxylic acids by a reduction-arenesulfonylation-reduction sequence.<sup>17b</sup> Hydroboration of each leads to a pair of alcohols. Although the pair from 2-*exo*-methyl-5-norbornene (18) can be analyzed by capillary gas chromatography, preparative separation is difficult. However, the two alcohols from the *endo* olefin 14 are readily separable by preparative gas chromatography. In this way, 5-*endo*-methyl-2-*exo*-norbornanol (19) and 6-*endo*-methyl-2-*exo*-norbornanol (20) are obtained in pure form. Conversion of 19 and 20 to *p*-bromobenzenesulfonates (19-OBs and 20-OBs) and solvolyses of the latter<sup>18</sup> under nonequilibrating conditions establish the identities of the entire series. Thus, 19-OBs gives 19, 21, and the characteristic products derived from the complex series of transannular hydride shifts and Wagner-Meerwein rearrangements summarized in the scheme given elsewhere,<sup>19</sup> but does not give any 20 or

whereas 20-OBs, being blocked from that mechanism by the barrier to secondary-secondary vicinal hydride shift, merely regenerates 20 and the Wagner-Meerwein related 22 in addition to tertiary product in 6,2 shift.<sup>18</sup> The data combined with the reasonable assumption that these kinetically controlled solvolyses give *exo* products<sup>7</sup> are consistent with only one mutation, which is shown in Scheme I.

Scheme I

**3-Methyl-2-exo-norbornanols.** Deaminative nitration of 3-*exo*-methyl-2-*endo*-norbornylamine was expected to give a complex mixture of products. Fractional crystallization of the acid phthalate and saponification gave an alcohol "isoaposenol," which was assigned the structure *syn*-7-methyl-2-*exo*-norbornanol.<sup>20</sup> The location and stereochemistry of the methyl

group at C-7 were established by oxidation to "isoaposenic acid" (24), which was not identical with but was

20) G. Komppa and S. Beckmann, *Ann.*, 523, 68 (1936).

epimerizable to an acid "cis-aposenic acid," 25, prepared by structurally unquestionable synthesis and shown to have *cis*-carboxyl groups. If the less stable of the two acids is the "all-*cis*" form 24, then "isoaposenol" is 23. The *anti* isomer 26 was never isolated pure,<sup>20</sup> but its presence in the deamination mixture from 3-*endo*- and/or -*exo*-methyl-2-*endo*- and/or -*exo*-norbornylamine was inferred from the isolation of "cis-aposenic acid" (25) from the oxidation of a fraction of the mixed alcohols obtained by combining reaction products from both amines. Although a detailed reexamination of the deaminations is reported elsewhere,<sup>18</sup> we note here merely that alcohol 26 is formed in substantial quantity from the 3-*endo*-methyl-2-*exo* amine and also (as the acetate) from acetolysis of the corresponding arenesulfonates. It can readily be isolated in pure form by preparative vapor chromatography.<sup>18</sup> The structure assigned is supported on the circumstantial grounds that 26 formed by carbonium ion process is invariably accompanied by an approximately equal amount of its Wagner-Meerwein relative 3-*endo*-methyl-2-*exo*-norbornanol (5).<sup>18</sup> Also, the nmr spectrum of the acetate of 26 shows a sharp doublet ( $J = 7$  cps) at  $\delta$  0.9 (superimposed on diffuse absorption), attributable to the C-7 methyl group, and a clean doublet of doublets centered around  $\delta$  4.5, attributable to the *endo*-C-2 proton coupled with the appropriate<sup>10</sup> coupling constants ( $J_{2,3 \text{ trans}} = 3$  cps,  $J_{2,3 \text{ cis}} = 7$  cps) to the C-3 *exo* and *endo* protons, respectively. The absence of further splitting ( $J \cong 1$  cps)<sup>10</sup> of this multiplet is consistent with the absence of a 7-*anti* proton. Further, chemical evidence for the structure is provided by a number of transformations.<sup>21</sup>

**1- and 2-Methyl-2-norbornanols and 1-Methyl-3-norbornanols.** The 2-methyl-2-norbornanols 27 and 28 and the 1-methyl-2-norbornanols 29 and 30 are well known,<sup>6,12,22</sup> and require no further comment. 1-

Methyl-3-*exo*-norbornanol (31) is formed together with 1-methyl-3-*exo*-norbornanol (29) in the hydroboration of 1-methyl-2-bornornene. The epimer 1-methyl-3-*endo*-norborneol (32) is obtained in a mixture with 31 by oxidation of 31 and hydride reduction of the derived ketone.

### Experimental Section<sup>23</sup>

Vapor chromatographic (vpc) analyses were performed with capillary columns on Barber-Colman gas chromatographs,

(21) Paper III: J. A. Berson and R. G. Bergman, *J. Am. Chem. Soc.*, 89, 2569 (1967).

(22) N. J. Toivonen, E. Siltanen, and K. Ojala, *Ann. Acad. Sci. Fennicae, Ser. AII*, No. 64 (1955).

(23) Microanalyses were performed by Spang Microanalytical Laboratories, Ann Arbor, Mich.

Models 61-C and 5000, using argon carrier gas and radium or tritium ionization detectors. Column stationary phases were TCEP (tri- $\beta$ -cyanoethoxypropane, 250 ft) (column L) and two polypropylene glycol columns (Ucon 50-HB-2000, 100 and 250 ft) (columns M and N). Preparative vpc separations were accomplished with Wilkens (now Varian) Aerograph Models A-90-P and A-700 Autoprep instruments equipped with thermal conductivity detectors and using helium carrier gas. Tricyanoethoxypropane (TCEP) stationary phase as obtained commercially always contained impurities which showed infrared absorption at 2.7–3.1 and 5.9–6.3  $\mu$ . Although good packed columns could be prepared with this material, it was unsuitable for capillary work, since columns prepared from it bled excessively and had short useful lifetimes. The TCEP was purified by percolation (as a solution in pure methylene chloride) through Woelm alumina, basic, activity grade III. The material so prepared gave relatively durable capillary columns. Table I lists the packed and capillary columns used in this work.

Table I. Vapor Chromatographic Columns

Proton magnetic resonance spectra (nmr) were obtained with a Varian Associates A-60 instrument. Samples of about 50 mg were dissolved in 250  $\mu$ l of carbon tetrachloride containing tetramethylsilane as internal standard, and resonance positions are reported in parts per million downfield from tetramethylsilane ( $\delta$  units). The  $J$  values reported are approximate multiplet spacings which in some but not all cases are the same as true coupling constants.

Infrared spectra of neat films (unless otherwise indicated) were taken with the Perkin-Elmer Model 137 or Beckman Model IR-8 instruments.

A number of carboxylic acids and the corresponding methyl esters were prepared for use as reference compounds in this work. Some of the acids but none of the esters had been previously reported. Analytical data for the esters and a new acid 35 are given in Table II. The table also lists melting points for the previously known acids, which were prepared by literature procedures. The methyl esters were prepared by the action of ethereal diazomethane on the acids followed by bulb-to-bulb distillation. They were homogeneous by capillary vpc.

3-endo-Methyl-2-endo-carboxymethoxy-5-norbornene (35, R = CH<sub>3</sub>) was obtained in the following manner. A crude acidic fraction was derived from mother liquors from the preparation of 3-exo-methyl-5-norbornene-2-endo-carboxylic acid (33, R = H) by zinc reduction of the corresponding iodolactone.<sup>6</sup> This material was treated with diazomethane to give a mixture of 33, 34, and 35 (R = CH<sub>3</sub>) in proportions that varied with the purity of the iodolactone starting material and the amount of 33 (R = H) removed in

the crystallization. Preparative vpc on column H, afforded pure 35 (R = CH<sub>3</sub>), homogeneous by capillary vpc under conditions where 33 and 34 were cleanly detectable. The retention times on both capillary columns were identical with those of the minor component of the 96:4 two-component mixture produced by epimerization of 34 (R = CH<sub>3</sub>) in boiling methanol-sodium methoxide for 3 hr. The nmr spectrum showed a methyl doublet ( $J$  = 7 cps) at  $\delta$  0.75, a methoxyl singlet at 3.55, a complex series of multiplets between 1.3 and 2.9 (6-proton intensity), and a 2-proton signal in the olefinic region centered near 6.15 as a pair of four-line multiplets separated by 17 cps,  $J$  = 3 cps. The corresponding acid, 35 (R = H), was obtained in small yield by saponifying the ester with aqueous methanolic sodium hydroxide and recrystallizing the resulting product from acetonitrile. The corresponding saturated ester, 37 (R = CH<sub>3</sub>), was isolated by preparative vpc on column H.

The *exo-cis* unsaturated ester 36 (R = CH<sub>3</sub>) was obtained only in admixture with the *trans* form 33 by epimerization of the latter.

The TCEP capillary column separated the four unsaturated esters in the following order of elution: 34, 33, 35, 36.

3-exo-Methyl-2-endo-acetylnorbornane (11). Pure, racemic 3-exo-methyl-2-endo-norbornanecarboxylic acid (12), 27.0 g (0.24 mole), was treated with 35 ml of freshly distilled thionyl chloride for 10 hr at room temperature. The excess reagent was distilled off and the acid chloride distilled at 86–87° (20 mm) to yield 39.6 g of product (96%).

Dimethylcadmium reagent was prepared by adding 60 g (0.63 mole) of dry methyl bromide to 13.5 g (0.55 g-atom) of magnesium turnings in 400 ml of ether, letting the Grignard reagent stand 3 hr, and then adding with cooling 58 g (0.32 mole) of anhydrous cadmium chloride and allowing the mixture to stir for 2 hr at room temperature.

The oxidation also was achieved with *m*-chloroperbenzoic acid in methylene chloride. The material was worked up as in the *endo* series (method A). The crude residue contained no starting ketone. The acetate was distilled at 76–77° (7 mm) to give a colorless liquid, homogeneous by capillary vpc (column L), in 79% yield. Infrared spectrum and vpc retention times were identical with the material obtained by hydroboration of 2-methyl-2-norbornene, oxidation, and acetylation. The latter is the more convenient method for obtaining either racemic or optically active acetate 8. The nmr spectrum showed bands for COCH<sub>3</sub>,  $\delta$  1.93, singlet; CHCH<sub>3</sub>,  $\delta$  1.04, doublet,  $J = 7$  cps; C-2-*endo*-H,  $\delta$  3.96, doublet of doublets,  $J \sim 2.5, 2.5$  cps.

Anal. Calcd for C<sub>10</sub>H<sub>16</sub>O<sub>2</sub>: C, 71.39; H, 9.59. Found: C, 71.17; H, 9.44.

**From Hydroboration of 2-Methyl-2-norbornene (9).** A three-necked round-bottomed flask equipped with a magnetic stirring apparatus was charged with 22.5 g of 2-methyl-2-norbornene,<sup>9</sup> 3.70 g of sodium borohydride, and 150 ml of tetrahydrofuran (THF), distilled from LiAlH<sub>4</sub> before use. A solution of 16.7 ml of boron trifluoride etherate (freshly distilled) dissolved in 50 ml of THF was then added dropwise to the flask, with rapid stirring. A white precipitate formed during the addition. After the resulting mixture had been stirred overnight, it was cooled to –5° in an ice-salt bath, and 5 ml of water was slowly added, followed by 50 ml of a 10% aqueous solution of sodium hydroxide. The flask was then allowed to warm to room temperature while 55 ml of a 30% aqueous solution of hydrogen peroxide was added dropwise with stirring.

After the resulting two-phase mixture had been stirred for 3 hr, the phases were separated, and the aqueous layer extracted twice with pentane. The combined organic phases were washed three times with a 10% aqueous solution of sodium hydroxide and once with a solution of saturated NaCl, and dried overnight over solid sodium sulfate. The liquid was then decanted and the pentane carefully removed by distillation through a Vigreux column on a steam bath, leaving 25.1 g (96%) of alcohol as a slightly greenish oil which slowly solidified into a gummy mass. The alcohol was converted to 3-*endo*-methyl-2-*exo*-norbornyl acetate in the usual way and the acetate distilled bulb to bulb to give a water-white, sweet-smelling oil which had an infrared spectrum and vpc retention time identical with those of the acetate obtained as above from 3-*endo*-methyl-2-*exo*-acetylnorbornane. The acetate obtained from the hydroboration route was contaminated with about 6% of presumably isomeric materials. It could be purified by automatic chromatography (Wilkens A-700 "Autoprep" instrument) on column E; by this procedure it was obtained 99.0% pure after one pass, as determined by analysis on capillary columns L and N-1.

**3-*endo*-Methyl-2-*exo*-norbornanol (5).** The purified 3-*endo*-methyl-2-*exo*-norbornyl acetate (8) described above was reduced to the corresponding alcohol (5) with lithium aluminum hydride in the standard way. The alcohol was again obtained as a semisolid which was sublimed at 120° (15 mm) to give fine, white crystals, mp 95.5–97.0°.

Anal. Calcd for C<sub>9</sub>H<sub>14</sub>O: C, 76.14; H, 11.18. Found: C, 76.14; H, 11.25.

**3-*endo*-Methyl-2-*exo*-norbornyl acid phthalate** was obtained after two recrystallizations from heptane as a white powder, mp 89.5–90.0°.

Anal. Calcd for C<sub>16</sub>H<sub>18</sub>O<sub>4</sub>: C, 70.06; H, 6.61. Found: C, 70.20; H, 6.57.

**3-*endo*-Methyl-2-*exo*-norbornyl *p*-toluenesulfonate** was formed when 0.79 g of the alcohol in 3 ml of pyridine was stirred at 0° and treated portionwise with 1.20 g of solid *p*-toluenesulfonyl chloride (freshly recrystallized from carbon tetrachloride). After 4 days at 5°, the mixture was poured onto cracked ice and extracted with ether. The ether solution, after thorough washing with water and brine, was dried over sodium sulfate, decanted, and evaporated. The residue was dried *in vacuo* (0.1 mm for 3 hr) to give 1.50 g (84%) of a solid which, after four recrystallizations from heptane, had mp 58.8–59.8°.

Anal. Calcd for C<sub>15</sub>H<sub>18</sub>O<sub>3</sub>S: C, 64.26; H, 7.19; S, 11.44. Found: C, 63.98; H, 7.06; S, 11.31.

The corresponding *p*-bromobenzenesulfonate was obtained by a procedure which differed only in that the reaction mixture was stored in the cold for only 36 hr. The compound was obtained as white crystals, mp 71–72°, from heptane; it was moderately stable at –5° but decomposed to a black, intractable semisolid on standing overnight at room temperature.

Anal. Calcd for C<sub>14</sub>H<sub>16</sub>O<sub>3</sub>Br: C, 48.68; H, 4.96; S, 9.29; Br, 23.15. Found: C, 48.56; H, 4.96; S, 9.34; Br, 23.21.

**5- and 6-*endo*-Methyl-2-*exo*-norbornyl Acetates (Acetates of 19 and 20).** Pure, racemic 5-norbornene-2-*endo*-carboxylic acid was converted to 5-*endo*-methyl-2-norbornene (14) via the methanol and its *p*-bromobenzenesulfonate according to the method previously reported.<sup>17b</sup> To a slurry of 35 ml of purified tetrahydrofuran (distilled from lithium aluminum hydride after reflux over potassium hydroxide), 4.68 g (43.3 mmoles) of the pure hydrocarbon, and 0.85 g (22.4 mmoles) of sodium borohydride was slowly added 3.7 ml of boron trifluoride etherate in 10 ml of solvent with vigorous stirring. The hydroboration mixture was allowed to stir for 18 hr. With cautious dropwise addition of 10 ml of 10% sodium hydroxide solution and 10 ml of 30% hydrogen peroxide solution, the very exothermic oxidation was achieved within a 1-hr period. The addition of water and extraction with ether four times, back washing the combined organic layers three times with saturated brine, drying over sodium sulfate, and careful concentration yielded the crude alcohol mixture which was inseparable on capillary columns L or N. Acetylation gave a mixture of acetates, which showed on capillary vpc on column L two main peaks contaminated by less than 2% unidentified olefins and 1% isomeric acetates. The acetates of 20 and 19 were present in the ratio of 56.3:43.7 (average over two separate hydroborations and work-ups, standard deviation =  $\pm 0.3\%$  absolute) in order of increasing retention time on column L.

The two major acetate components could be preparatively separated with relative ease on columns A or E.

**6-*endo*-Methyl-2-*exo*-norbornyl acetate**, the first main fraction of the preceding hydroboration mixture, was repassed once again on column E to give colorless liquid acetate, pure by capillary vpc. This compound was not present in the products resulting from the acetolysis of arenesulfonates of 3-*exo*-methyl-2-*endo*-norbornanol (1a) or 5-*endo*-methyl-2-*exo*-norbornanol (19).

Anal. Calcd for C<sub>10</sub>H<sub>16</sub>O<sub>2</sub>: C, 71.39; H, 9.59. Found: C, 71.24; H, 9.69.

**6-*endo*-Methyl-2-*exo*-norbornanol (20)** was obtained from its acetate by reduction with lithium aluminum hydride in the usual manner. Bulb-to-bulb distillation at reduced pressure produced a low melting solid, not completely liquified at room temperature.

Anal. Calcd for C<sub>9</sub>H<sub>14</sub>O: C, 76.14; H, 11.18. Found: C, 75.92; H, 11.06.

The *p*-nitrobenzoate, after two recrystallizations from absolute methanol, melted at 108.5–109.0°.

Anal. Calcd for C<sub>15</sub>H<sub>17</sub>NO<sub>4</sub>: C, 65.44; H, 6.22. Found: C, 65.29; H, 6.34.

The *p*-toluenesulfonate 20-OTs was isolated as an oil which began to crystallize after 2 months standing at –20°. Recrystallization from pentane-ethyl acetate at about –50° gave white plates, mp 37.5–38.5°, which were not stable for more than 1 day at room temperature.

The *p*-bromobenzenesulfonate 20-OBs was isolated as white needles while wet with pyridine. Recrystallization from pentane or vacuum suction to remove the pyridine resulted in the spontaneous decomposition of the *p*-bromobenzenesulfonate within 5 min at 0°.

**6-*endo*-Methyl-2-norbornanone.** A small amount of the alcohol 20 was oxidized with Jones reagent in acetone to yield the ketone contaminated with about 5–8% alcohol. The ketone was purified by preparative vpc on column G to yield a low melting, waxy solid.

Anal. Calcd for C<sub>9</sub>H<sub>14</sub>O: C, 77.38; H, 9.74. Found: C, 77.51; H, 9.84.

The 2,4-dinitrophenylhydrazones was obtained as orange crystals, mp 129.4–130.0°.

Anal. Calcd for C<sub>14</sub>H<sub>16</sub>N<sub>4</sub>O<sub>4</sub>: C, 55.26; H, 5.30; N, 18.41. Found: C, 55.12; H, 5.37; N, 18.35.

**5-*endo*-Methyl-2-*exo*-norbornyl acetate**, the component of longer retention time from the hydroboration of 5-*endo*-methylnorbornene, was repassed once again on column E to give a liquid acetate pure by capillary vpc. This material had a retention time (column L) identical with that of one of the products of the acetolysis of 3-*exo*-methyl-2-*endo*-norbornyl *p*-bromobenzenesulfonate.

Anal. Calcd for C<sub>10</sub>H<sub>16</sub>O<sub>2</sub>: C, 71.39; H, 9.59. Found: C, 71.36; H, 9.50.

**5-*endo*-Methyl-2-*exo*-norbornanol (19)** was obtained from the acetate by reduction with lithium aluminum hydride. After bulb-to-bulb distillation it was a viscous mass.

Anal. Calcd for C<sub>9</sub>H<sub>14</sub>O: C, 76.14; H, 11.18. Found: C, 76.29; H, 11.12.

*p*-nitrobenzoate had mp 56.5–57.0° (from absolute methanol). *ul.* Calcd for  $C_{14}H_{17}NO_4$ : C, 65.44; H, 6.22. Found: 22; H, 6.17.

*p*-toluenesulfonate of this alcohol remained a liquid in our . The *p*-bromobenzenesulfonate, 19-OBs, decomposed in a manner to that of 20.

*endo*-Methyl-2-norbornanone. A small sample of alcohol 19 converted to the ketone with Jones reagent in acetone and the product purified on column G to yield a clear liquid which crystallized below room temperature.

*ul.* Calcd for  $C_8H_{12}O$ : C, 77.38; H, 9.74. Found: C, 77.38; H, 9.92.

2,4-dinitrophenylhydrazone of the ketone was obtained as a solid, mp 151.0–151.5° (absolute methanol).

*ul.* Calcd for  $C_{14}H_{14}N_4O_4$ : C, 55.26; H, 5.30; N, 18.41. Found: C, 55.22; H, 5.36; N, 18.25.

*endo* 6-*exo*-Methyl-2-*exo*-norbornyl acetates (acetates of 21 and 22) were obtained from pure 5-norbornene-2-*exo*-carboxylic acid by the same procedure used for the 5- and 6-*endo*-methyl compounds. Analysis with capillary column L showed two main peaks to be present in a ratio of 1:1 and two smaller peaks, each about 3% of the total. Presumably the latter peaks represent a small amount of *endo*-hydroboration product. The merging of the two major peaks, the 6-*exo*-methyl-2-*exo*-norbornyl acetate (22), was completely absent from the acetolysis products of 19-OBs or the arenesulfonates of 1a. Its retention time was identical with that of one of the two products from acetolysis of 20-OBs, the second product being the acetate of 20.<sup>12</sup> The other major peak (acetate of 21) had a retention time identical

with that of one of the products from the acetolysis of 19-OBs and 1a.<sup>12</sup>

1-Methyl-3-*exo*-norbornanol (31) was formed by alkaline hydrogen peroxide oxidation of the residues from partial asymmetric hydroboration<sup>13</sup> of 1-methyl-2-norbornene,<sup>9</sup> a reaction that had been carried out in another study.<sup>14</sup> The resulting mixture of 1-methyl-2-*exo*- and 1-methyl-3-*exo*-norbornanols (29 and 31) was separated by vpc on column D (31 emerged second) and then on column F. Alcohol 31 was obtained as a waxy solid.

*Anal.* Calcd for  $C_8H_{14}O$ : C, 76.14; H, 11.18. Found: C, 75.97; H, 11.29.

The *p*-nitrobenzoate was recrystallized from methanol and had mp 93–94°.

*Anal.* Calcd for  $C_{14}H_{17}O_4N$ : C, 65.44; H, 6.22; N, 5.09. Found: C, 65.35; H, 6.12; N, 5.06.

The acetate was a liquid.

*Anal.* Calcd for  $C_{10}H_{16}O_2$ : C, 71.39; H, 9.59. Found: C, 71.53; H, 9.62.

The *p*-toluenesulfonate was a liquid that could not be induced to crystallize at –65° in pentane. It was homogeneous by thin layer chromatography.

Jones oxidation of 31 followed by lithium aluminum hydride reduction of the resulting ketone gave a two-component mixture of 31 and a much larger amount of another alcohol, presumably 1-methyl-3-*endo*-norbornanol (32), which emerged just before 31 on column L.

## The Chemistry of Methylnorbornyl Cations. III. Configurational Correlation of 2,3- and 2,7-Substituted Norbornyl Derivatives by Way of 3-Substituted Nortricyclenes<sup>1</sup>

Jerome A. Berson and Robert G. Bergman<sup>2</sup>

Contribution from the Department of Chemistry, University of Wisconsin,  
Madison, Wisconsin. Received October 31, 1966

**Abstract:** The relative configurations and optical rotations of *anti*-7-methyl-2-*exo*- and -3-*endo*-methyl-2-*exo*-norbornyl acetates are established by two independent correlations. Both correlations involve 3-nortricyclene derivatives as relay compounds, and the transformations provide absolute configurations and rotations of these substances also.

ough a network of absolute and relative configurational correlations among 1- and 2-substituted bicycloheptane and bicyclooctane derivatives has been constructed,<sup>3</sup> only a few correlations between 2- and 7-substituted norbornanes are available.

In studying one aspect of the mechanism of carbocation rearrangements of methyl-labeled norbornyl cations,<sup>4</sup> we found the need to establish such correlations. Since the methods adopted to achieve involve nortricyclic relay compounds, the present work also provides the first determinations of absolute configuration of nortricyclenes.

The support of part of this work by the National Institutes of Health and Metabolic Diseases through Grant No. AM-07505 is fully acknowledged.

Acetolysis of the *p*-bromobenzenesulfonate (1b) of optically active 3-*endo*-methyl-2-*exo*-norborneol (1a) gives a mixture of products<sup>4</sup> from which are isolated (–)-3-*endo*-methyl-2-*exo*-norbornyl acetate (1c), identical in sign and magnitude of rotation with 1c obtained by direct acetylation of 1a, and (–)-7-*anti*-methyl-2-*exo*-norbornyl acetate (2b). (The rotations refer to the sodium D line.) The absolute configuration of (–)-1c is established by oxidation and methylation to (+)-camphenilone (3).<sup>4</sup> For reasons discussed elsewhere,<sup>4</sup> a correlation of 1b and 2b is mechanistically significant but cannot be based on the assumption that (–)-1c and (–)-2b are related as simple Wagner–Meerwein

1a, X = OH  
b, X = OBs  
(–)-c, X = OAc

(+)-3

isomers. The configuration of 2b must accordingly be established by independent means. In the following reaction diagrams, which illustrate two such correlations, the indicated configurations are absolute.

**Scheme I.** The general objective of Scheme I is the correlation of *anti*-7-methyl-2-*exo*-norbornyl acetate (2b)<sup>4</sup> with *exo*-norbornanecarboxylic ester (11). Oxidation of alcohol 2a, configurationally related to (–)-acetate 2b, gives a ketone 4, which is converted to the *p*-toluenesulfonylhydrazone. Pyrolysis of the *dry* sodium salt *in vacuo* smoothly converts it to (+)-3-methylnor-tricyclene (6).<sup>5</sup> The same hydrocarbon is obtained by a reduction–arenesulfonylation–reduction sequence from (+)-methyl 3-nortricyclenecarboxylate (8), the corresponding active acid 7 being available by resolution *via* the cinchonidine salt. The ester (+)-8 serves as a relay for the entire series. Catalytic hydrogenation (40 psi, acetic acid solvent, platinum oxide catalyst) breaks the cyclopropane ring of (+)-8 to give a mixture of about equal parts of methyl 7-norbornanecarboxylate (10) and (+)-methyl 2-*exo*-norbornanecarboxylate (11). Very little of the epimeric methyl 2-*endo*-norbornanecarboxylate, the product of the third possible mode of ring cleavage, is formed under these conditions. A small amount of unreacted tricyclic ester 7 of undiminished rotation can be recovered; this gives assurance that partial epimerization (that is, racemization) of 7 does not accompany hydrogenation. From the known<sup>3a</sup> configuration of (+)-11, the configurations of the substances of Scheme I follow.

This correlation, although straightforward in establishing configurational relationships, leaves something to be desired when quantitative comparisons of optical purities of solvolysis substrate 1b and product 2b are to be made. Thus, Scheme I correlates the magnitudes of rotation of 2b and 11, without reliance on an outside standard of optical purity, from the product of the three rotation ratios 2b:6, 6:8, and 8:11. However, the maximum rotation of 1b is correlated with that of camphenilone 3,<sup>4</sup> a substance not included in Scheme I.

(5) (a) Cf. W. R. Bamford and T. S. Stevens, *J. Chem. Soc.*, 4735 (1952); (b) L. Friedman and H. Shechter, *J. Am. Chem. Soc.*, 81, 5512 (1959); (c) J. W. Powell and M. C. Whiting, *Tetrahedron*, 7, 305 (1959); (d) see, especially, G. M. Kaufman, J. A. Smith, G. G. Vander Stouw, and H. Shechter, *J. Am. Chem. Soc.*, 87, 935 (1965).

A comparison of maximum rotations of 11 and 3 is not now available by direct correlation. The maximum rotation of 11 rests on isotopic dilution analysis,<sup>4</sup> whereas that of 3 has an entirely separate basis.<sup>3a</sup> Therefore, since there is no common relay, the 11:3 rotation ratio and hence the crucial 2b:1b ratio is subject to a pyramiding of the errors inherent in each separate rotation. This is probably the cause of the somewhat low apparent value (92% retention) found<sup>4</sup> when the data of Scheme I are used to calculate the stereochemical result of the 1b → 2b reaction. Furthermore, the exact magnitude of the absolute rotation of the *exo* ester 11 is subject to some question, since it was originally prepared<sup>6</sup> from a sample of 2-*exo*-5-norbornenecarboxylic ester which was subsequently shown<sup>3a</sup> to contain a small amount of impurity. It seems desirable therefore to provide a correlation free of these disadvantages. This is given in Scheme II, where the rotations of 1b and 2b are related through that of a common reference, the tricyclic hydrocarbon 6.

**Scheme II.** A sample of optically active 1a (at the same level of optical purity as the sulfonate 1b used for the solvolysis from which (–)-2b is isolated) is oxidized to the ketone 12 with Jones reagent (chromic acid–acetone). Although the oxidation proceeds in good yield, it is accompanied by epimerization, the product being a 90:10 mixture of the *endo*- and *exo*-methyl ketones, 12 and 14. The small amount of 14 is removed by vapor chromatography and the pure *endo* ketone 12 is transformed into the *p*-toluenesulfonylhydrazone (13). Hydrazone formation is slow, and if allowed to proceed too long in an effort to force complete conversion, is accompanied by partial epimerization. This becomes evident when the corresponding sodium salt is pyrolyzed to the tricyclic hydrocarbon (+)-6. The structural change converts epimerism to enantiomerism, and the rotation of the (+)-6 obtained in this way (+14.7°) is significantly lower than that (+16.3°) obtained from (–)-2b in Scheme I. This is a particularly awkward result because it is not obvious which of the two epimeric hydrazones the hydrocarbon product is derived from, and hence the correlation of (–)-1c

(6) J. A. Berson and D. A. Ben-Efraim, *ibid.*, 81, 4083 (1959).

(-)-6, already seen to be unreliable in magnitude, actually might be reversed in sign. (In its reversal of sign would be not inconceivable the rotation were identical in magnitude.) A solution of the epimeric *exo* ketone 14 is therefore needed to make a firm correlation. Deliberate epimerization of the above mixture of optically active ketones enriches the 14 content to 40%. Isolation of pure 14 by vapor chromatography, conversion to the *p*-toluenesulfonylhydrazone (under milder conditions than before), and reduction of the sodium salt give (-)-6 with an optical rotation ( $-16.4^\circ$ ) opposite in sign but essentially equal in magnitude to that obtained from (-)-2b. This rules out any possibility of a sign inversion in the correlation of (-)-1c and (+)-6. Since no obvious mechanism for racemization is available in the (-)-2b conversion of Scheme I, the production of (-)-6 from the same magnitude of rotation as (+)-6 from the same source, (-)-1c, must mean that the (-)-2b, and (-)-6 samples all have the same optical

The data show that 2b (in 95% ethanol) has the same specific rotation of 1c (in absolute ethanol) at the same level of optical purity.

shows that acetolysis of 1b gives 2b by simple *Wittig*-Meerwein change and with complete retention of optical purity. The mechanistic significance of this observation is discussed in an accompanying paper.<sup>4</sup>

## Experimental Section

Details of vapor chromatographic and other standard techniques are given in paper II.<sup>7</sup>

**1. Correlation of 7-anti-Methyl-2-*exo*-norbornyl Acetate with 3-Methylnortricyclene [(+)-6].** Acetate 2b (0.58 g) of  $[\alpha]_D^{25} -3.19^\circ$  (95% ethanol)<sup>4</sup> was reduced to the corresponding alcohol and oxidized with Jones reagent to 7-anti-norbornanone (4). The procedure used was identical with that employed in the oxidation of 3-*endo*-methyl-2-*exo*-norbornanol. An infrared spectrum of the ketone obtained in this way showed a strong C=O band at  $5.72 \mu$  and no O-H absorption. The material was chromatographed on column B at  $120^\circ$  and ob-

tained 99.5% pure by capillary vpc. It was distilled bulb to bulb and used without further characterization. The ketone (0.156 g) was dissolved in 3 ml of absolute ethanol and 0.234 g of *p*-toluenesulfonylhydrazine was added. The resulting mixture was heated at reflux on a steam bath for 1.5 hr, after which it was cooled and allowed to stand overnight at room temperature. Addition of water caused precipitation of a white solid; this was removed by extracting three times with  $\text{CHCl}_3$ . The combined chloroform extracts were washed with 5% HCl and saturated NaCl and dried over magnesium sulfate. Filtration and evaporation at the aspirator left 0.354 g of white solid (96% yield), presumed to be 7-anti-methyl-2-norbornyl *p*-toluenesulfonylhydrazone. An infrared spectrum of the material, showing bands at  $3.1$  (N-H),  $6.01$  (C=N), and  $6.29 \mu$  (aromatic), was consistent with the proposed structure. The lack of C=O absorption indicated that the ketone had reacted completely. An nmr spectrum in  $\text{CDCl}_3$  showed absorption from  $\delta$  7.2 to 8.0 (4 H) assigned to the aromatic protons, and a singlet at  $\delta$  2.4 (3 H) due to the aromatic methyl group. A doublet assigned to the 7-methyl group ( $J = 7$  cps) was centered at  $\delta$  0.9, superimposed on complex absorption, arising from the nitrogen proton and the remaining protons of the norbornyl skeleton, running from  $\delta$  0.9 to 2.3 (total 13 H).

The sodium salt of the *p*-toluenesulfonylhydrazone was prepared by the following procedure. (It is extremely important that the sodium salt formation be carried out under scrupulously anhydrous conditions, since the salt is quite hygroscopic and the presence of water prevents the formation of tricyclic hydrocarbon in the subsequent pyrolysis.) The entire sample of *p*-toluenesulfonylhydrazone (0.354 g) was placed in a 25-ml, round-bottomed flask, which had been swept with dry nitrogen. A 15-ml portion of tetrahydrofuran, freshly distilled from lithium aluminum hydride, was added quickly to the flask, along with 0.143 g of sodium methoxide. The resulting mixture was stirred overnight at room temperature, protected by a blanket of dry nitrogen. Evaporation of the solvent and drying *in vacuo* overnight (0.2 mm) left a white solid caked to the walls of the flask. The vacuum was broken with dry nitrogen and the salt loosened from the sides of the flask with a spatula in a dry atmosphere.

The flask was then attached, *via* a Pyrex tube, to a receiver cooled in a Dry Ice-acetone bath, the system evacuated to a pressure of 18 mm (normal vacuum pump pressures, of the order of 0.2 mm, prevent efficient trapping of the volatile hydrocarbon), and the flask was heated with an air gun. At the reaction temperature (estimated to be about  $110^\circ$ ), the salt decomposed completely in about 10 sec, evolving gas and bubbling off hydrocarbon. A slightly tan solid was left in the flask, and about 0.080 g of volatile product had collected in the trap. A vpc analysis of this material on column O indicated it to be almost completely (ca. 97%) 3-methylnortricyclene contaminated with a small amount of a second material. No diazo compound was detectable (infrared spectrum), but vpc analysis on column L at  $125^\circ$  indicated the presence of a small amount (ca. 1%) of 7-anti-methyl-2-norbornanone (4).

L. Berson, A. W. McRowe, R. G. Bergman, and D. Houston, *J. Am. Chem. Soc.*, **89**, 2563 (1967).

The tricyclic hydrocarbon (+)-6 was collected vpc pure from chromatography on column H-1 at 80°. Its specific rotation was found to be  $[\alpha]^{25}_D +16.3^\circ$  (95% ethanol), and its infrared spectrum was identical with that of the hydrocarbon obtained from nortricyclene-3-carbinyl *p*-bromobenzenesulfonate (9).

**Scheme I. Optical Activation of Nortricyclene-3-carboxylic Acid (7).** The cinchonidine salt was prepared in methanol, 95% ethanol, and acetone, but crystals were obtained only from the latter solvent. A solution of 79.0 g of the acid<sup>8</sup> in 250 ml of acetone was heated to boiling on a steam bath, and 189 g of solid cinchonidine was added. After having been heated at reflux for 0.5 hr, the mixture was filtered, concentrated on the steam bath, and cooled to room temperature. The solution was allowed to stand for 8 days at room temperature, and the crystals were collected on a Büchner funnel. Four recrystallizations from boiling acetone gave a total of 110 g (wet) of salt in the head crop. A 50.0-g portion of this material was reconverted to carboxylic acid in the manner described for the ephedrine salt of 3-endo-methyl-2-exo-norbornyl acid phthalate,<sup>4</sup> yielding 14.6 g of optically active material as a greenish oil. Reaction with diazomethane in ether solution and evaporation of the solvent gave methyl 3-nortricyclenecarboxylate (8) which distilled as a clear oil shown to be 98.5% pure by capillary vpc. The nmr and infrared spectra were identical with those of the racemic compound. A sample was chromatographed on column E at 175° to give material of greater than 99.9% purity which was redistilled bulb to bulb. This material had  $[\alpha]^{25}_D +15.3^\circ$  (95% ethanol).

**Scheme I. (+)-Nortricyclene-3-carbinyl *p*-Bromobenzenesulfonate [(+)-9].** This derivative (13.5 g) was prepared from 6.4 g of optically active methyl 3-nortricyclenecarboxylate [(+)-8] as described by Gajewski<sup>9</sup> and others<sup>10</sup> for the racemic series. Spectral properties of the sulfonate, as well as of its carbinol precursor, were identical with those of the racemic compounds.

The carbinol was also converted to (+)-nortricyclene-3-carbinyl acetate (also shown to be identical with the racemic compound), which was distilled, chromatographed on column E at 180° to give material completely pure by capillary vpc on column N-1, and redistilled bulb to bulb to give material of  $[\alpha]^{25}_D +17.9^\circ$  (methanol).

**Scheme I. (+)-3-Methylnortricyclene [(+)-6].** A small sample of nortricyclene-3-carbinyl *p*-bromobenzenesulfonate [(+)-9], prepared as above, was dissolved in dry ether and treated with 0.15 g of lithium aluminum hydride in a dry atmosphere. The solution bubbled vigorously for about 15 min and was heated at reflux overnight. The flask was cooled and the mixture worked up with sodium sulfate in the standard way, except that the pentane extracts were washed thoroughly with 20% sodium hydroxide solution before drying. Careful removal of the pentane through a Vigreux column left 0.30 g of greenish oil which was chromatographed on column H-1 at 80°. This gave capillary vpc pure (column O) material; the infrared spectrum showed readings at: 3.25, 3.4, 3.45, 6.9, 7.3, 7.4, 7.7, 7.8, 8.0, 10.34, and 11.1  $\mu$  (CCl<sub>4</sub>). An nmr spectrum showed complex absorption from  $\delta$  1.3 to 3.3; no other signals were observed.

*Anal.* Calcd for C<sub>8</sub>H<sub>12</sub>: C, 88.82; H, 11.18. Found: C, 88.79; H, 11.23.

A rotation was taken on the vpc pure material. It exhibited  $[\alpha]^{25}_D +28.0^\circ$  (95% ethanol).

**Scheme I. Correlation of (+)-Methyl 3-Nortricyclenecarboxylate (8) with (+)-Methyl 2-*exo*-Norbornanecarboxylate (11).** A 1.0-g portion of the above sample of (+)-8,  $[\alpha]_D +15.3^\circ$  (95% ethanol), was hydrogenated over 1.5 g of platinum oxide in 50 ml of dry acetic acid at 40 psi until uptake ceased. The resulting mixture was passed through diatomaceous earth, diluted with water, and extracted with pentane. The combined pentane fractions were washed with water and then with saturated sodium bicarbonate solution until the washings were basic. After washing with saturated brine and drying over magnesium sulfate, the pentane was carefully removed through a Vigreux column, leaving about 0.9 g of clear oil which contained (by capillary vpc) 5% unreacted methyl 3-nortricyclenecarboxylate (8), 47% methyl 2-*exo*-norbornane-

carboxylate (11), and 48% methyl 7-norbornanecarboxylate (10). The bicyclic esters were separated from the starting material on column E at 178°. The tricyclic ester 8 obtained was 99.0% pure by capillary vpc, and its rotation was unchanged compared with that taken before the hydrogenation, proving that it had not epimerized during the reaction. The active ester 11 was separated from its necessarily inactive isomer 10 by chromatography on column B at 120°. In this way 11 could be obtained 99.0% pure (contaminated with 1.0% of the 7-substituted isomer 10). After redistillation it had  $[\alpha]^{25}_D +11.5^\circ$  (95% ethanol).

The relative amounts of each of the two norbornanecarboxylic esters produced were estimated by capillary vpc peak areas (column N-1), after calibration with mixtures of authentic samples of known composition. A mixture containing 49.3% of methyl 2-*exo*-norbornanecarboxylate 11 and 50.7% of its 7-substituted isomer 10 had a specific rotation of  $[\alpha]^{25}_D +5.58^\circ$ . Using the value of  $+11.5^\circ$  (*vide infra*) for the specific rotation of 11 obtained on the 99.0% pure isomer as described above, the rotation of the 7-carbomethoxynorbornane could be calculated to be 0° within experimental error.

**Scheme II. The 3-Methyl-2-norbornanones.** Optically active 3-endo-methyl-2-*exo*-norbornyl acetate (1c) of specific rotation  $[\alpha]^{25}_D -1.85^\circ$  (absolute ethanol)<sup>4</sup> was reconverted to the corresponding alcohol 1a with lithium aluminum hydride. The alcohol obtained in this way (about 3.1 g), dissolved in 50 ml of acetone, was cooled to 0° in an ice bath, and 8 ml of Jones reagent<sup>11</sup> was added slowly with rapid stirring of the cold solution. The mixture was stirred for 2 min after the addition, poured onto cracked ice, salted heavily, and extracted four times with pentane. After combination, the organic extracts were washed with water and saturated sodium chloride and dried over sodium sulfate. Decantation of the liquid and careful removal of the pentane left 2.2 g (69% yield) of material which had a decidedly camphoraceous odor. The product was identified as a mixture of 90% 3-endo-methyl-2-norbornanone (12) and 10% of its 3-*exo*-methyl epimer 14,<sup>12</sup> along with minor amounts of other unidentified products.

**Scheme II. Epimerization of 3-Methyl-2-norbornanones.** A 0.70-g sample of the above ketone mixture was dissolved in 20 ml of dry methanol. Sodium was cut freshly under heptane and 0.115 g added to the solution; the resulting mixture was heated at reflux for 2.5 hr in a nitrogen atmosphere (it was found by trials with racemic samples of this mixture that longer reflux times produced only disappearance of product due to condensation, and no further equilibration of the monomeric ketones). The reaction mixture was quenched with water, salted heavily, and extracted four times with pentane. After the combined pentane fractions had been washed with water and brine, they were dried over magnesium sulfate and concentrated under a Vigreux column on the steam bath. Vpc analysis of the residue indicated the presence of about 40% 3-*exo*-methyl-2-norbornanone (14) and 60% of its 3-endo-methyl epimer 12. These were separated on column B at 130°; each was obtained pure by capillary vpc.

**Scheme II. Optical Correlation of 3-endo-Methyl-2-*exo*-norbornyl Acetate [(−)-1c] with 3-Methylnortricyclene [(+)-6].** A sample of acetate (−)-1c of rotation  $[\alpha]^{25}_D -1.85^\circ$  (absolute ethanol) was converted to the ketones 12 and 14 as described directly above. The *p*-toluenesulfonylhydrazone of 3-endo-methyl-2-norbornanone (12) was prepared from the ketone (purified by vpc) by the same procedure used for 7-*anti*-methyl-2-norbornanone (4), except that 1.5 hr of reflux time was insufficient to completely convert the ketone to its derivative. The reflux was, therefore, continued overnight, and the product worked up and converted to the hydrocarbon as described for 4. The pyrolysis reaction mixture from the sodium salt of 3-endo-methyl-2-norbornyl *p*-toluenesulfonylhydrazone consisted of 6% of an unidentified compound, 3.2% of a material whose retention time was identical with that of 2-methyl-2-norbornene, 1% 3-endo-methyl-2-norbornanone (12), and the remainder 3-methylnortricyclene [(+)-6]. The tricyclic hydrocarbon was separated on column G-1 at 95°. It was pure by vpc and had  $[\alpha]^{25}_D +14.7^\circ$  (95% ethanol).

Pure 3-*exo*-methyl-2-norbornanone obtained from the same optically active source was converted to a *p*-toluenesulfonylhydrazone derivative in the same way as 12 except that the reaction mixture was heated at reflux only 3 hr; the infrared spectrum of the white solid obtained indicated contamination from about 5% of

(8) Racemic material was prepared according to J. D. Roberts, E. R. Trumbull, Jr., W. Bennett, and R. Armstrong, *J. Am. Chem. Soc.*, **72**, 3116 (1950).

ketone. This mixture was carried through to the hydrocarbon as before. The pyrolysis product in this case, despite scrupulous vacuum drying of the sodium salt, was contaminated with about 30% of tetrahydrofuran. The other products consisted of about 6% 3-*endo*-methyl-2-norbornanone (12), 1.5% 2-methyl-2-norbornene, 1.5% of an unidentified compound, and the remainder 3-methylnorbornene. The tricyclic hydrocarbon was again

separated by preparative vpc on column G-1 at 130°, shown by infrared to be identical with material obtained from previous preparations, and its purity checked by capillary vpc. It had  $[\alpha]^{25}_D -16.4^\circ$  (95% ethanol), a value essentially identical in magnitude and opposite in sign with that of hydrocarbon obtained above in Scheme I directly from 7-*anti*-methyl-2-*exo*-norbornyl acetate (2b).

## The Chemistry of Methylnorbornyl Cations. IV. Ratios of Rates of Nucleophilic Capture of the Cations at Wagner–Meerwein-Related Sites<sup>1</sup>

Jerome A. Berson, Arthur W. McRowe, and Robert G. Bergman<sup>2</sup>

Contribution from the Department of Chemistry, University of Wisconsin, Madison, Wisconsin. Received October 31, 1966

**Abstract:** A detailed study of the product distributions from solvolyses and deaminations of a number of precursors of methylnorbornyl cations permits the evaluation of the relative rates of capture of these species at each of the two Wagner–Meerwein-related sites. A direct steric effect on nucleophilic approach and another effect which opposes developing hydrogen–methyl repulsions in the transition state are noted. The characteristic capture ratios observed in the solvolytically produced ions apply also to the deaminatively produced ones, the major difference between the two processes being the excess of “direct substitution” observed in deamination. A comparison of the deamination results with those obtained earlier in the unsubstituted norbornyl case reveals that the “direct substitution” is very sensitive to a  $\beta$ -methyl steric effect, which causes a complete reversal of the stereochemistry of the process.

The summarizing rearrangement scheme given in paper I<sup>3</sup> of this series outlines the interconversions of a set of “core” methylnorbornyl cations A, B, and C by 6,2-hydride shifts (Chart I) and their escape to

“periphery” cations A<sub>1</sub>, B<sub>1</sub> ( $\equiv$  B<sub>2</sub>), and C<sub>1</sub> by 3,2-hydride shifts. The present paper provides evidence for this scheme from studies of the products derived from solvolyses of various methylnorbornyl derivatives.

Chart I. “Core” System

(1) (a) Support of part of this work by the National Institute of Arthritis and Metabolic Diseases through Grant No. AM-07505 and by the National Science Foundation is gratefully acknowledged. (b) A preliminary report of some of this work has appeared: J. A. Berson, A.

W. McRowe, and R. G. Bergman, *J. Am. Chem. Soc.*, **88**, 1067 (1966). (2) National Institutes of Health Predoctoral Fellow, 1964–1966.

(3) J. A. Berson, J. H. Hammons, A. W. McRowe, R. G. Bergman, A. Remanick, and D. Houston, *J. Am. Chem. Soc.*, **89**, 2561 (1967).

In a previous study,<sup>4</sup> entry into the "core" set of cations was effected *via* cation C, generated by formolysis of *syn*-7-methyl-2-*exo*-norbornyl acid phthalate (3a). The major products reported<sup>4</sup> were the formates

of 5-*exo*-methyl-2-*exo*-norborneol (6b), assumed<sup>4</sup> to be derived by 6,2-hydride shift, and 1-methyl-2-*exo*-norborneol (10b), assumed<sup>4</sup> to be derived by *endo*-3,2-hydride shift. Longer exposure of the products to the formolysis conditions caused conversion to 10b in high yield. It seemed likely, however, that a number of other products might be formed, at least under kinetically controlled conditions.<sup>5</sup> Gas chromatography provides a means of demonstrating this and now reveals the presence in such solvolysis mixtures of all six products expected from the "core" set of cations as well as three additional ones with structures 10, 8, and 9 derived from the "periphery" cation A<sub>1</sub>. The origin of the latter products from A<sub>1</sub> rather than from the enantiomerically related cation C<sub>2</sub> can be demonstrated in the optically active series,<sup>6</sup> but for the present, the distinction between 10, 8, and 9 on the one hand and their respective enantiomers on the other is ignored.

Entry into the "core" cycle is effected *via* cation A when 3-*endo*-methyl-2-*exo*-norbornylamine (1f) is nitrosated or when the corresponding *p*-bromobenzenesulfonate (1e) is solvolyzed; *via* cation C by deamination of 3-*exo*-methyl-2-*endo*-norbornylamine (7f) or the corresponding *p*-bromobenzenesulfonate (7e); and *via* cation B by solvolysis of 5-*exo*- or 5-*endo*-methyl-2-*exo*-nor-

bornyl *p*-bromobenzenesulfonate (6e or 5e). The "periphery" cation A<sub>1</sub> (C<sub>2</sub>) is encountered in solvolyses of 1-methyl-2-*exo*-norbornyl *p*-toluenesulfonate, in deamination of 2-*endo*-methyl-2-*exo*-norbornylamine,<sup>7</sup> in solvolysis of the corresponding chloride,<sup>8</sup> and also in leakage to the "periphery" from the "core" series. Solvolyses of 6-*endo*-methyl-2-*exo*-norbornyl *p*-bromobenzenesulfonate (11e) generate cation B<sub>1</sub> (≡B<sub>2</sub>), which is captured to give 11c or 11d and the 6-*exo*-methyl isomer 12c, or 12d, in addition to products derived from 6,2-H shift.

**Solvolyses.** Table I lists the product distributions from solvolytic generation of cations A, B, and C (the "core" series) at 95–100° in several solvent systems. The cations generated at the points of entry into and exit from the scheme are indicated alongside each starting material and product. The percentages of products derived by capture of the *initial* cation (without hydride shift) are given in boldface type.

Very little leakage from the "core" to the "periphery" series of cations by vicinal hydride shift occurs under kinetically controlled conditions (excess of buffer). When the acid generated in solvolysis is allowed to accumulate, however, the kinetically controlled product composition shifts, and the "core" products are gradually converted to 1-methyl-2-*exo* product 10 derived from secondary-tertiary cation A<sub>1</sub>, which represents a thermodynamic valley. The accumulation of product 10 under reversible conditions had been observed<sup>4</sup> qualitatively in unbuffered solvolysis of 3a. The very low yield of products from cation A<sub>1</sub> (Table I) under buffered conditions results therefore from the escape of the bulk of the material at earlier exits in the mechanism. Under prolonged exposure of the 1-methyl-2-*exo* product 10 to equilibrating conditions, still slower processes occur. One of these is secondary-secondary 3,2-hydride shift to give cation D, which

phthalate. <sup>b</sup> *p*-Toluenesulfonate, fourfold excess sodium acetate buffer. <sup>c</sup> *p*-Nitrobenzenesulfonate, fourfold excess sodium formate. <sup>d</sup> *p*-Bromobenzenesulfonate, 25-fold excess pyridine buffer, 40–50% by volume ethanol or 50% by volume dioxane. <sup>e</sup> *p*-Nitrobenzenesulfonate, 2.5-fold excess sodium acetate buffer. <sup>f</sup> *p*-Bromobenzenesulfonate, 10% molar excess sodium acetate buffer. 60% of this fraction was 6-*exo*-methyl-2-*exo* product (12b). The remainder was a mixture of about equal parts of 6-*endo*-methyl-2-*endo*, 1-methyl-2-*endo*, and 1-methyl-3-*exo* products. <sup>g</sup> This fraction consisted of a 9.8:1 mixture of 6-*exo*-methyl-2-*exo*-norbornyl acetate. <sup>h</sup> A mixture (8.2:1) of the 6-methyl-2-*exo* norbornanols, the *endo* isomer 11d being the minor component.

1-methyl-3-*exo* product, and cation B<sub>1</sub> (≡B<sub>2</sub>), leads to 6-*exo*- and 6-*endo*-methyl-2-*exo* products. Significantly, under buffered conditions in all media examined, only the first nine products listed in Table I are formed. These are the ones expected from Scheme I of paper I.

**Hydride Shift vs. Solvent Capture.** Table I shows that regardless of the point of entry into the reaction, products from each of the "core" cations A, B, and C are always found. Thus, 6,2-hydride shift is competitive with capture by solvent. The hydride shifts are intramolecular. Sodium acetate buffer gives the typical mixture of products, about 60% of which (Table I) arise from hydride shift, and 40% contain only about 0.03 D per molecule. In contrast, the 1-methyl-2-*exo*-norbornyl product that predominates in unbuffered medium incorporates substantial amounts of deuterium.

The percent of product derived from the cation generated at entrance (boldface entries in Table I) is higher in aqueous medium than in acetic or formic acid. In this sense, this effect suggests that capture by solvent becomes relatively more important as the nucleophilicity increases. Similar behavior is observed in the 7,7-dimethyl-3,3-dimethyl-5,5-dimethyl norbornyl and in the 2,3-di-<sup>14</sup>C-labeled norbornyl<sup>10a</sup> and norbornyl cases.<sup>10b</sup> In terms of the adjacent hydride shift, this interpretation amounts to the proposal that the rate constant (which includes a solvent concentration term) for capture of the initial cation X, is higher in the more nucleophilic solvent. Strictly speaking, this is applicable to the observed result only for "unsubstituted" (isotopically labeled) norbornyl systems where the fractions of the total product derived from hydride shift (F<sub>h</sub>) and with (F<sub>y</sub> + F<sub>z</sub>) hydride shift are given by eqs 1 and 2. If it is assumed that the hydride shift is insensitive to solvent, the fraction of X cap-

tured as P<sub>x</sub> necessarily increases as k<sub>x</sub> increases. The

$$F_x = P_x / (P_x + P_y + P_z) = (k_1 + k_2) / (3k_1 + k_2) \quad (1)$$

$$F_y + F_z = (P_y + P_z) / (P_x + P_y + P_z) = 2k_1 / (3k_1 + k_2) \quad (2)$$

simplicity of eq 1 arises from symmetry; in the "unsubstituted" norbornyl system, where X, Y, and Z are structurally equivalent, all the hydride shift rate constants (k<sub>1</sub> through k<sub>4</sub>) are identical (except for a negligible isotope effect), as are all the capture rate constants (k<sub>x</sub>, k<sub>y</sub>, and k<sub>z</sub>). Furthermore, these respond equally to a change of solvent. The symmetrical situation is discussed further elsewhere,<sup>6</sup> but we note here that in the general case the equivalences are perturbed by substitution, and large changes in the rate constants result. The solvent effect is then less readily interpretable, since the fraction P<sub>x</sub>/(P<sub>x</sub> + P<sub>y</sub> + P<sub>z</sub>) is a much more complex function of the rate constants, any or all of which (k<sub>x</sub>, k<sub>y</sub>, and k<sub>z</sub> in particular) may have varying solvent sensitivity.

The general pattern of Table I makes it clear that the rates of solvent capture, 6,2-hydride shift, and tertiary-secondary 3,2-hydride shift are all competitive. Were 6,2 shift overwhelmingly fast relative to the other two processes, the product distribution would be insensitive not only to solvent variation but also to the point of entry into the "core" cycle. This is clearly not the case. Even with cation B<sub>1</sub> (≡B<sub>2</sub>) derived from 6-methyl substrate, where 6,2-hydride shift is especially favorable because it leads to tertiary cation C<sub>2</sub>, one still sees a substantial amount of direct solvent capture (Table I).

Tertiary cation C<sub>2</sub> (A<sub>1</sub>), whether generated from the 6-methyl system B<sub>1</sub> by hydride shift or directly from 1-methyl-2-*exo* precursor, does not revert to any of the

secondary cations of Table I under kinetically controlled conditions.

**Relative Rates of Capture of the Cations at Wagner-Meerwein-Related Sites.** Each of the "core" cations A, B, and C can be captured at two nonequivalent Wagner-Meerwein-related sites. Arrangement of the products of Table I in Wagner-Meerwein pairs permits an inspection of the relative rates of capture at the two available positions in each. The data are given in Table II, where the results of solvolyses that generate the 6-methyl cation B<sub>1</sub> are also listed. Note that B<sub>1</sub> also suffers extensive hydride shift into the tertiary system (cation C<sub>2</sub>).

With cations A and B, the capture ratios show virtually no position selectivity and, furthermore, are quite insensitive to solvent or to the point of entry into the "core" cycle. Thus, cation A gives 3-*endo*-methyl- and 7-*anti*-methyl-2-*exo* products (1 and 2) in the ratio 1.08 ± 0.06, and cation B gives 5-*endo*-methyl- and 5-*exo*-methyl-2-*exo* products (5 and 6) in the ratio 1.23 ± 0.12, the values being the averages of results obtained by generating the cations in six different ways each. The methyl group in both cations is remote from the reaction site and can exert little effect on the approach of a nucleophilic solvent molecule (SOH) from the *exo* direction.

As an alternative, one might consider a trivial explanation for the constancy of the ratios based on the

assumption that equilibration of starting areneculfonate *via* ion-pair return provides a common pool of mixed substrates regardless of the point of entry. This can be ruled out immediately, since it would require not only constant capture ratios for each cation but constant ratios of *all* products, in conflict with the data of Table I. The invariance of the product ratios from cations A and B is most simply explained in terms of characteristic ratios for cation capture. These seem to be quite insensitive to solvent.

Cation C shows a marked preference for attack at C-2 to give *syn*-7-methyl-2-*exo* product rather than at C-1 to give 3-*exo*-methyl-2-*exo* product, as would be expected from the more severe steric shielding of C-1 by the methyl group. The apparent fluctuation in the product ratio from C is probably attributable to the lower accuracy of analyses for these two products. The data also suggest a slower over-all rate of capture (or a higher rate of hydride shift) for cation C than for cations A or B, since the total amount of C-derived products (3 and 4) when entry is made at C is substantially less than the total amount of A-derived or B-derived products when entry is made at either of those points.

In cation B<sub>1</sub> even though the methyl group now does not interfere directly with the line of approach of solvent to the *exo* side of C-1 or C-2, there is an 8- to 10-fold preference for attack at C-2 to give 6-*exo*-methyl-2-*exo*

rather than at C-1 to give 6-*endo*-methyl-2-*exo* product. A simple interpretation of the preference is based on the repulsive interactions that develop in transition states. One of these involves the site of attack, where a hydrogen is driven upwards toward another hydrogen or a methyl group at C-6. It seems reasonable to assume that the H-CH<sub>3</sub> repulsion rated during attack at C-1 would be the more serious one, and that consequently attack at C-2 would predominate.

The steric effect in the product-forming step is associated with a difference in free energy between the transition states leading to 12 and 11, since the ground states are either the same or effectively the same (a non nonclassical ion B<sub>1</sub>, or if the opponents of this species insist, a pair of rapidly equilibrating classical ions). Whatever its detailed nature, a kind of steric destabilization similar to that in the transition state leading to 6-*endo*-methyl-2-*exo* product must also be present, by virtue of an approximately microscopic reverse relationship, in the solvolysis of a corresponding 6-*endo*-methyl-2-*exo* substrate. If this energy argument is the predominant one and if it is greater in the transition state than in the solvolysis ground state, the result would be a lower solvolysis rate for a 6-methyl derivative than for the unsubstituted norbornyl system itself. The observation<sup>11</sup> that 6,6-di-*tert*-butyl-2-*exo*-norbornyl *p*-toluenesulfonate acetolyzes much slower than the corresponding norbornyl derivative is consistent with these requirements. It is interesting to conclude, as a referee has urged, that the steric interference in question is greater in the transition state, which would be attributable to a decreased C-6 distance resulting from carbon bridging in a nonclassical structure. In our opinion, however, this probably would be an overinterpretation, since substitution of methyl for hydrogen in the norbornyl system unavoidably introduces numerous steric interactions in addition to the one depicted in B<sub>1</sub> in both ground and transition states. The net increase or decrease in solvolysis rate as compared to the parent system is a function of these difficultly separable effects. For the present, we merely point out that the results given here provide experimental evidence for transition-state steric effects in 6-*endo*-methyl-2-*exo*-norbornyl solvolyses. Future analyses of substituent effects on solvolysis rates of norbornyl derivatives must take factors of this kind into account.

**Deamination of 3-*exo*-Methyl-2-*endo*-norbornylamine and 3-*endo*-Methyl-2-*exo*-norbornylamine (1f).** Komppe and Beckmann<sup>12</sup> prepared these two amines in what must have been<sup>13</sup> essentially pure form from the corresponding acids. From deamination with sodium nitrite in aqueous acetic acid they reported isolation

(as acid phthalates) of two alcohols, *syn*-7-methyl-2-*exo*-norborneol (3d) and 3-*exo*-methyl-2-*endo*-norborneol (7d). In addition, they inferred that another product, *anti*-7-methyl-2-*exo*-norborneol (2d), was present in the reaction mixture from one (or both) of the amines.<sup>14</sup> In our hands, substantial quantities of the *endo* alcohol 7d, the *syn*-7-methyl-2-*exo* alcohol 3d, or the corresponding acetates are formed only from *endo* amine 7f. The product distributions from the two amine hydrochlorides are given in Table III. The conditions for deamination of 1f are those of Komppe and Beckmann<sup>12</sup> (aqueous acetic acid, sodium nitrite); these give a mixture of alcohols and acetates. Deamination of 7f is effected in dry acetic acid or in water, where the products are acetates or alcohols, respectively.

The most striking difference between the deamination (Table III) and solvolysis (Table I) results is the large amount of 3-*exo*-methyl-2-*endo*-norbornyl derivative (7d or 7c) formed in deaminations of 3-*exo*-methyl-2-*endo*-norbornylamine 7f. This product is not formed in deaminations of the 3-*endo*-methyl-2-*exo* amine 1f or in solvolyses of any of the substrates of Table I. Qualitatively, formation of 7c with retention of configuration from amine 7f recalls previous observations with the unsubstituted parent compound *endo*-norbornylamine.<sup>15,16</sup> The deamination of that substance in acetic acid gave 16% acetate products 21–23% of which were formed by a path in which substitution (by some mechanism not yet clear<sup>16</sup>) occurred at the site of the original amino group and 77–79% of which came from “racemizing” processes involving nonclassical ions or their structural equivalents. The 21–23% “direct substitution” figure is matched fairly well by the 28% of product 7c, 3-*exo*-methyl-2-*endo*-norbornyl acetate. Another 4% of product with unrearranged structure, 3-*exo*-methyl-2-*exo*-norbornyl acetate (4c), is also formed, but it seems likely that most if not all of this material results from capture of the familiar cation C rather than by “direct substitution.” This conclusion is based on the demonstrably reasonable assumption that the characteristic cation capture ratios observed for Wagner–Meerwein pairs in solvolyses of arenesulfonates (Table II) apply, at least roughly, to deaminations as well. For example, the 1:2 ratios of Table III from amine 7f (where neither 1 nor 2 can be formed by direct substitution) are 1.28 and 0.94. Although measured on minor components and hence not very accurate, these are in agreement with the average value 1.08 of Table II. Similarly, the 5:6 ratio of 1.6, again measured on a minor pair of products, corresponds moderately well to the value 1.23 found in Table II. Thus, if any appreciable fraction of the *cis*-*exo* product 4 were being formed by “direct substitution,” the 3:4 ratio should be less than that found in solvolysis. This solvolytic value, which because of experimental difficulties is not very accurately measurable, ranges between 4 and 8 (Table II), whereas the deaminative 3:4 ratio (Table III) is in the range 11–12. Although the discrepancy, if real, is not readily interpretable, the data argue against the idea of an

	2-endo	C <sub>1</sub> (A <sub>1</sub> )	1	1	0	0
	3-exo		0	0	46.8	28.4

origin of a substantial amount of product 4 in a "direct substitution" path.

In the deamination of 3-*endo*-methyl-2-*exo*-norbornylamine (1f), at most a small amount of the product seems to arise from direct substitution. The ratios of products 2:1 in both the alcohols (X = OH) and acetates (X = OAc) are about 1.5, and if this is assumed to be meaningfully higher than the ratio 1.08 found in solvolyses (Table II), as much as 9% of the alcohol and 6% of the acetate of the 3-*endo*-methyl-2-*exo* structure (1d or 1c) might be "direct substitution" product. There is no 3-*endo*-methyl-2-*endo* product (less than 1% would have been detected), so that the 6-9% figures represent the total "direct substitution." Thus, "direct substitution" is considerably less important with the 3-*endo*-methyl-2-*exo* amine 1f than with the 3-*exo*-methyl-2-*endo* isomer 7f. This corresponds to the pattern in the unsubstituted norbornylamine case,<sup>16</sup> where the *exo* amine gave less "direct substitution" product than the *endo*.

The division of the "direct substitution" products between inversion (*exo* amine → *endo* alcohol, *endo*

amine → *exo* alcohol) and retention modes for the two *trans*-3-methylnorbornylamines (7f and 1f) and for the two unsubstituted cases (13 and 14) are summarized in Table IV. The major effect of substituting a 3-*trans*-methyl for 3-hydrogen in both the *endo*- and *exo*-amino

compounds (13 → 7f, 14 → 1f) is to suppress the inverting deaminative "direct substitution." The result is consistent with several mechanistic rationalizations for the process and hence not decisive. Nevertheless, it does demonstrate a rather high degree of steric sensitivity to  $\beta$  substitution. This sensitivity is particularly pronounced in the case of 3-*exo*-methyl-2-*endo*-norbornylamine (7f), where the *exo*-methyl group forces virtually exclusive *endo* substitution (retention), a complete reversal of the result obtained<sup>16</sup> in the unsubstituted

#### IV. Inversion and Retention in the Deaminative Substitution<sup>16</sup>

Reference 16. <sup>b</sup> In water. <sup>c</sup> In dry acetic acid. <sup>d</sup> In aqueous acid.

The stereochemistry of "direct substitution" contrasts markedly with that in the lithium aluminum hydride reduction of the corresponding ketone, 3-methyl-2-norbornanone, which gives predominantly the product of *exo*-hydride attack, 3-*exo*-methyl-2-norbornanol (7d).<sup>13,14,17</sup> The observed stereochemistry of hydride reduction of 2-norbornanones has been used<sup>6,18</sup> as a model of the stereochemistry to be expected in the nucleophilic capture of hypothetical 2-norbornyl cations. The discrepancy between the results in the 3-*exo*-methyl system must mean that the model is not uniformly applicable or that a classical carbonium ion is not the product-forming intermediate in the "direct substitution." In view of the widespread intervention of ion pair or complex intermediates in deaminations<sup>19</sup> which can well produce the observed stereochemical pattern, it seems unnecessary to abandon the stereochemical model.

#### Experimental Section

Acetic acid and formic acid were dried according to procedures in the literature.<sup>20,21</sup> Acetolyses were carried out at 95–100° under the conditions given in Table I. Cold solutions of reactive substrates were injected into stirred solvolysis media. The preparation of the substrates is described elsewhere.<sup>22</sup> Acetolyses and formolyses were carried out at initial concentrations of about 0.5 M buffer and 0.1 M substrate. Hydrolyses used about 2.5 M pyridine and about 0.1 M substrate. As has been shown elsewhere,<sup>6</sup> the material balance in the analysis of 3-*exo*-methyl-2-*endo*-norbornyl *p*-bromobenzenesulfonate is essentially quantitative. Product identification was carried out for the runs of Table I by actual isolation<sup>6</sup> and/or by comparison with known samples<sup>23</sup> on two different capillary columns using procedures already described. Detector response to isomers was considered uniform. Samples of 0.2 μl were injected with flow ratios of 100:1 to 400:1. Detector response was linear for this size sample if column "bleed" was not excessive.

Peak areas were determined by triangulation and were reproducible to better than 0.5% between two major well-resolved peaks and to 1–2% between minor ones. Comparisons between peaks of very different size were subject to greater error. Analyses were carried out with columns L and N<sup>22</sup> on acetate mixtures. Alcohols were acetylated and formates were saponified to alcohols and acetylated for analysis. Most of the peaks were resolved to base line, but *syn*-7-methyl-, 5-*exo*-methyl-, and 3-*exo*-methyl-2-*exo*-norbornyl acetates emerged within 1 min of each other and were difficult to analyze with high accuracy. The tertiary acetate, 2-*endo*-methyl-2-*exo*-norbornyl acetate, separated from its epimer 2-*exo*-methyl-2-*endo*- and from its Wagner-Meerwein relative 1-methyl-2-*exo*-norbornyl acetate, whereas the alcohol 1-methyl-2-*exo*-norbornanol separated well from the two tertiary alcohols. All three of these separated well from the remainder of the product mixture. The amount of 2-*exo*-methyl-2-*endo* material was, therefore, determined by difference between the acetate and alcohol chromatograms.

Except for the slow conversion among these three "tertiary-related" acetates,<sup>6</sup> the remainder of the product composition was essentially unchanged upon reexposure to the reaction conditions in buffered medium. In particular, no interconversion between the "tertiary-related" products and the group of secondary products derived from the "core" cations occurred, nor was there appreciable interconversion among the latter secondary products, at least in buffered acetolyses and hydrolyses. In formolysis, even in the presence of buffer, slow conversion to 1-methyl-2-*exo* product was observed. Entry *via* cation C in Table I was effected by a brief (5 min) formolysis of 3-*exo*-methyl-2-*endo*-norbornyl *p*-nitrobenzenesulfonate. This sufficed to achieve essentially complete reaction, but the product mixture was essentially unchanged after 20-min additional exposure and therefore presumably reflects rate control. After 2 hr of further exposure, however, the accumulation of 1-methyl-2-*exo* product became detectable. Unbuffered formolysis of the *p*-bromobenzenesulfonate gave 1-methyl-2-*exo* formate as the major product.

**3-*exo*-Methyl-2-*endo*-norbornylamine (7f).** A mixture of 13.1 g (85 mmoles) of pure racemic 3-*exo*-methyl-2-*endo*-norbornanecarboxylic acid, 95 ml of concentrated sulfuric acid, and 175 ml of reagent grade chloroform was chilled below 0°. In small portions, 6.5 g (100 mmoles) of sodium azide was added. The mixture was stirred at room temperature for 4 hr with a slow evolution of bubbles. Refluxing on a steam bath for 1.5 hr completed the reaction. The reaction mixture was cooled and 300 ml of 6 N sodium hydroxide solution was added to half-neutralize the acid; the addition of 350 ml of water was necessary to dissolve the salts formed.

The chloroform layer was drawn off from the chilled mixture, and the aqueous phase was washed with another 50 ml of solvent. The solution was made basic and more water was added. The free amine was extracted four times with a total of 600 ml of ether; the combined organic layers were washed once with 1 N sodium hydroxide solution and twice with saturated brine and dried over sodium sulfate.

The hydrochloride was precipitated by passing anhydrous hydrogen chloride gas over the chilled ether solution of the amine. The solid was filtered off and dried *in vacuo*. The yield of white, crystalline, nondeliquescent material was 12.5 g (91%). The material could be recrystallized from absolute ethanol.

The urea prepared in the manner described<sup>12</sup> gave sharply melting platelets, mp 204–205° (lit.<sup>12</sup> mp 200–201°).

**3-*endo*-Methyl-2-*exo*-norbornylamine (1f)** was prepared in a similar manner from the corresponding acid. The urea melted at 209–210° (lit.<sup>12</sup> mp 206–207°).

**Aqueous Deamination of 3-*exo*-Methyl-2-*endo*-norbornylamine (7f).** A solution of 1.9 g (27.5 mmoles) of sodium nitrite in 8 ml of water was added over a period of 10 min to a solution of 2.0 g (12.3 mmoles) of amine hydrochloride in 20 ml of water and five drops of 10% hydrochloric acid at 0°. The mixture, which became cloudy after 1 hr, was allowed to stand at 25° for 4 hr. No reddish nitrogen oxide fumes were noticed throughout the reaction course.

The acid solution was extracted with pentane three times; the combined organic layers were washed with saturated brine twice and dried over sodium sulfate. Careful concentration of the pentane solution yielded 1.5 g (96%) of a yellow oil as crude residue with the characteristic alcohol odor. An intense infrared spectrum of the neat liquid film indicated very strong hydroxyl peaks, no acetate at 5.75 or 8.0 μ, and only a very weak nitrate ester peak (6.1 μ). Capillary vpc on columns L or N indicated only one major peak (≥90% of total area). No 5-*exo* alcohol was present.

The crude product was acetylated directly with excess pyridine and acetic anhydride for 1.2 hr at 98°. After the reaction mixture was cooled to 25°, the excess anhydride was hydrolyzed with water for 2 hr. The mixture was then extracted three times with pentane, and the combined organic layers were washed with 10% hydrochloric acid, 10% sodium carbonate solution, and twice with saturated brine and dried over sodium sulfate.

The solution was carefully concentrated to yield a yellow residue which was distilled bulb to bulb at room temperature ( $3 \times 10^{-3}$  mm). The yield of colorless product was 1.8 g (90%) with the characteristically fruity odor. The infrared spectrum indicated it was all acetate; no hydroxyl absorptions remained. Analysis by capillary vpc on column L indicated two major peaks with small amounts of other acetate and unidentified olefins. The distribution of acetate products is given in Table III, in which the approximately 1% olefin formed is omitted. The errors in these percentages are estimated to be  $\pm 0.5\%$  absolute, although similar sized components can be compared with greater accuracy. The 5-*exo*-methyl-2-*exo* acetate 6c emerges between 4c (3-*exo*) and 3c (7-*syn*), and while it may be present to some extent, the limit of the determination of this component is about 1% for this case.

The two major components 3c and 7c could be preparatively separated on column E. After two successive passes, component 7c was free of any contamination. Its infrared spectrum was identical with that of the acetate prepared by the Baeyer-Villiger oxidation of 3-*exo*-methyl-2-*endo*-acetylnorbornane. It was reduced to 3-*exo*-methyl-2-*endo*-norbornanol (7d) with lithium aluminum hydride. The acid phthalate was prepared with equimolar quantities of phthalic anhydride and pyridine at 100° for 2 hr. This product, recrystallized thrice from hexane-benzene, melted at 126.5–128.0° (lit.<sup>13</sup> mp 131–132° for apocamphenyl acid phthalate). Mixture melting point with the acid phthalate from the Baeyer-Villiger product gave no depression.

Three passes of component 3c through column E still gave material contaminated with several per cent each of 4c and 5c. Reduction to the alcohols with lithium aluminum hydride and preparation of the acid phthalate were carried out in the usual manner. Four recrystallizations from hexane-benzene yielded material, mp 163.5–166.0° (lit.<sup>13</sup> mp 165–166° for "isoapocamphenyl acid phthalate"). Two more recrystallizations did not change the melting point. Saponification of the purified acid phthalate by alkaline steam distillation, ether extraction, drying, concentration, and acetylation in the usual manner gave back 7-*syn*-methyl-2-*exo*-norbornyl acetate (3c) contaminated with 3% 4c.

**Deamination of 3-*exo*-Methyl-2-*endo*-norbornylamine in Acetic Acid.** To 20 ml of dry acetic acid was added 0.43 g (2.66 mmoles) of amine hydrochloride. The solution was stirred and chilled to ca. 4° (solidification occurred at any lower temperature), and 0.43 g (6.2 mmoles) of finely crystalline sodium nitrite was added over a

20-min period. The solution became cloudy after 10 min and was allowed to stand at room temperature for 2 hr.

Ice water was added, and the mixture was extracted four times with pentane. The combined organic layers were washed once each with 2 *N* hydrochloric acid, saturated bicarbonate, and saturated brine, dried over sodium sulfate, and carefully concentrated. The pale yellow, mobile liquid product weighed 0.38 g (85%) and was directly analyzed on capillary columns L and N. Several per cent olefin and about 3% alcohols were formed in addition to the acetates. The minor classes of components were not readily identified. Only the relative acetate composition is reported in Table III.

A small portion of the acetate mixture was reduced with lithium aluminum hydride to the alcohol mixture. Analysis on capillary column L indicated the presence of a trace, estimated to be 0.02%, of the *t*-*exo* alcohol. No 1-methyl-2-*exo*-acetate or *t*-*endo* acetate was detected.

**Deamination of 3-*endo*-Methyl-2-*exo*-norbornylamine Hydrochloride.** A solution of 32.0 g of sodium nitrite in 100 ml of water was added dropwise to a stirred solution of 10.0 g of the amine hydrochloride in 75 ml of 50% (by volume) water-acetic acid at room temperature. Gas evolved at a moderate rate and an organic phase quickly separated. The mixture was allowed to stir at room temperature for 5 hr; it was then extracted four times with pentane. The pentane extracts were combined and washed with water and sodium bicarbonate until the washings were basic; they were then washed with saturated sodium chloride solution and dried over magnesium sulfate. Filtration and solvent evaporation with a Vigreux column left 6.0 g (67% yield) of a mixture whose composition is described in Table III. Distillation of the mixture bulb to bulb and acetylation of the distillate by the usual method gave a mixture of acetates whose composition was identical with the "acetate fraction" of Table III.

On column E at 180°, 3-*endo*-methyl-2-*exo*-norbornyl acetate (1c) and 7-*anti*-methyl-2-*exo*-norbornyl acetate (2c) could be separated from the minor products and obtained in relatively pure form. After reduction of 1c with lithium aluminum hydride, the alcohol 1d obtained was converted to its acid phthalate derivative 1a. Compounds 1c and 1d were identified by comparison of their infrared spectra and retention times on vpc with those of authentic materials.<sup>13</sup> Compound 1a had mp 89.5–90°, alone or mixed with an authentic sample<sup>13</sup> of 3-*endo*-methyl-2-*exo*-norbornyl acid phthalate. Compound 2c had a retention time on vpc different from that of 3-*exo*-methyl-2-*endo*-norbornyl acetate (7c) or 7-*syn*-methyl-2-*exo*-norbornyl acetate (3c). By lithium aluminum hydride reduction and treatment with phthalic anhydride, it was converted to 7-*anti*-methyl-2-*exo*-norbornyl acid phthalate (2a), mp 105.5–107.5° (from heptane).

Madison, Wisconsin, and University of Southern California, Los Angeles, California.  
Received October 31, 1966

**Abstract:** By correlations of the configuration and absolute rotation of 3-*endo*-methyl-2-*exo*-norbornyl *p*-bromobenzenesulfonate with those of the corresponding acetate (1) and the acetates of *anti*-7-methyl-2-*exo*-norbornanol (7) and 2-*endo*-methyl-2-*exo*-norbornanol (3) it is established that acetolysis of the sulfonate occurs to give acetates 1, 7, and 3 with high retention of optical purity. Acetates 1 and 7 have the configurational relationship of simple Wagner-Meerwein isomers; acetate 3 has the configuration expected of a product derived by direct *exo*-3,2-hydride shift in the 3-*endo*-methyl-2-norbornyl cation. The hydride shifts are intramolecular. From the product distributions and optical purity data, it can be shown that 3,2-hydride shift from a tertiary to a secondary center is at least 14 times as fast as secondary-secondary hydride shift, which in turn is at least 122 times slower than solvent capture in acetic acid at 100°. Previous data in the literature are interpreted to give a competition ratio for secondary-secondary 6,2-hydride shift *vs.* solvent capture (0.27 in acetic acid at 45°). The corresponding ratio for the tertiary-secondary case is evaluated from the product distribution in 6-methylnorbornyl solvolyses as 1.23 in acetic acid at 100°. A method for estimating the temperature correction to be applied and the first estimate of the minimum activation energy for capture of the norbornyl cation in acetic acid (4.65 kcal/mole) are given in the Appendix. The enhancement by methyl substitution of the rate of 6,2-hydride shift is estimated to be between 5- and 15-fold. The weakness of this effect in comparison to that in other systems is attributed to charge distribution in the transition state for the hydride shift, which is reasonably formulated as an edge-protonated cyclopropane.

The 3-*endo*-methyl-2-norbornyl cation (A)<sup>4</sup> can escape from the "core" cycle<sup>4</sup> of 6,2-hydride shifts a "periphery" system (A<sub>1</sub>) by *exo*-vicinal hydride

shift. The present paper demonstrates the occurrence of this reaction. The process serves as a standard of comparison for the 3-*exo*-methyl-2-norbornyl case (C), where stringent stereoelectronic prohibition of *endo*-vicinal hydride shift (to C<sub>2</sub>) is observed.<sup>5</sup> The chemistry of cation A also provides measures of the com-

petition between solvent capture and vicinal hydride shift and between secondary-secondary and tertiary-secondary vicinal hydride shift.

**Configurational Correlations.** The stereochemical relationships that provide the experimental basis for this study are established by a set of correlations anchored on (+)-camphenilone (2). Although the absolute configuration<sup>6</sup> (as shown) and approximate absolute rotation<sup>7</sup> of camphenilone are known, they become matters of no concern when both starting material (1,

**X = OBs) and product (3) are correlated to this ketone as a *common* relay.**

Optically active 3-*endo*-methyl-2-*exo*-norbornanol (1) (X = OH) is obtained by conversion of the racemic alcohol<sup>10</sup> to the acid phthalate and fractional crystallization of the ephedrine salt from acetone. Ten recrystallizations of the head crop, regeneration of the acid phthalate, and saponification give a 3-*endo*-methyl-2-*exo*-norbornanol (1, X = OH) which is converted on one hand to a levorotatory acetate (1, X = OAc),  $[\alpha]_D -1.85^\circ$  (absolute ethanol), and on the other, by oxidation with chromium trioxide to a mixture of 90% 3-*endo*- and 10% 3-*exo*-methyl-2-norbornanone. Methylation of this mixture (potassium *t*-butoxide, dimethyl sulfoxide, and methyl iodide) gives camphenilone [(+)-2],  $[\alpha]_D +16.5^\circ$  (benzene), which on the basis of the highest reported rotation<sup>7</sup> is 22% optically pure. Since optical fractionations are carefully avoided

throughout the sequence, the starting (–)-1a (X = OAc),  $[\alpha]_D -1.85^\circ$ , has the same optical purity as (+)-2,  $[\alpha]_D +16.5^\circ$ .

### Scheme I

• Experiment actually performed in enantiomeric series.

The tertiary product (3) expected from direct 3,2-hydride shift in cation A when the latter has the configuration related to that of (-)-1a (X = OAc) (Scheme I) might be derived conceptually from (+)-camphenilone (2) by reduction of the CO group to CH<sub>2</sub> and replacement of the *exo*-methyl group with acetoxy. This correlation can be achieved in practice by way of a relay compound, 2-*endo*-methyl-2-*exo*-norbornanecarboxylic acid, (-)-4, which had previously been correlated with (-)-camphenilane (6), which in turn

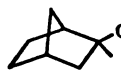

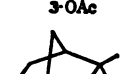

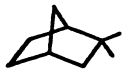

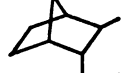

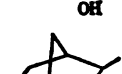

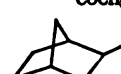

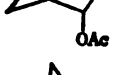

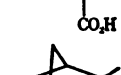

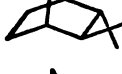

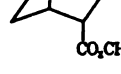

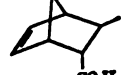

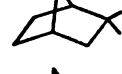

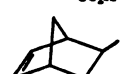

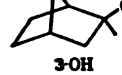

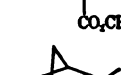

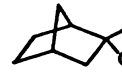

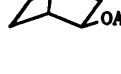

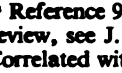

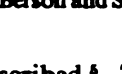

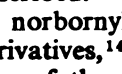

had been obtained<sup>8,11</sup> from (+)-camphenilone (2). Acid (−)-4 now is correlated to (−)-3 by two sequences (shown for economy of presentation in Scheme I in the series enantiomeric with that in which the experiments were actually performed): (i) by conversion to the methyl ketone and Baeyer–Villiger oxidation; (ii) by conversion to 2-*endo*-methyl-2-*exo*-norbornylamine by the Hofmann rearrangement,<sup>12a</sup> followed by nitrosative deamination<sup>12a</sup> of the latter in aqueous acetic acid to give the tertiary alcohol (+)-3-OH corresponding in configuration to (−)-3-OAc. The ratio of rotations of the tertiary alcohols (−)-3-OH obtained from the two routes is 1.23, in good agreement with the ratio of rotations of the starting acids 4 (i:ii = 1.30). Thus, the deaminatively produced alcohol has lost at most about 5% more optical purity than the oxidatively produced one. The correspondence strongly suggests that both sequences proceed with complete or nearly complete retention of optical purity. It would not have been surprising if the deamination, which probably passes through cation A<sub>1</sub>, actually did produce some racemization. At least under equilibrating conditions, this system rapidly loses all optical activity, presumably by intramolecular or intermolecular 6,2-hydride shift.<sup>12</sup> Under the strongly nucleophilic conditions used in the deamination, however, the cations probably are irreversibly captured, thus suppressing the competing

**6,2 shift.** Racemizing 6,2 shift is also slow even when cation  $A_1$  is produced under the not completely irreversible conditions in the solvolysis experiments to be

(11) (a) Out of concern that the strongly basic conditions of the Wolff-Kishner reduction<sup>8</sup> might have caused partial racemization of 2 or its hydrazone by homoenolization,<sup>11b</sup> we have confirmed the previous work<sup>8</sup> in both signs and magnitudes of rotation for the  $(+)-2 \rightarrow (-)-6$  correlation using conditions which, although basic, were quite different from the previous ones. The quantitative agreement between the results makes it highly unlikely that any racemization occurs. (b) A. Nickon and J. L. Lambert, *J. Am. Chem. Soc.*, **84**, 4604 (1962); **88**, 1905 (1966).

described.<sup>6</sup> This behavior contrasts markedly with that of norbornyl cation<sup>13</sup> and a number of substituted derivatives,<sup>14-16</sup> in which 6,2 shift competes with capture of the cations by solvent. An interpretation is offered based on the nonclassical structure, which because of the tendency of the methyl group to localize charge at C-1 has a smaller fraction of the positive charge at C-2 than in the unsubstituted case. This ef-

fect would decrease the rate of 6,2-hydride shift. Obviously, a parallel explanation could be given in terms of an interconverting pair of classical ions, one tertiary and the other secondary.

Correlation of the configuration and rotation of tertiary alcohol (+)-3-OH with those of (-)-norbornanone are also effected (Scheme I, iii) *via* the epimeric tertiary alcohol, which gives (+)-3-OH upon successive treatment with hydrochloric acid and alkali.<sup>12b</sup> The maximum rotation of 3-OH based on norbornanone is 11.0° (CHCl<sub>3</sub>), the same as that obtained by correlation with camphenilone. Since the norbornanone value (Table I) is ultimately based on an "absolute" method (isotopic dilution), the highest reported value for camphenilone must represent the rotation of optically pure material.

The correlations established in these studies are summarized in Table I, which also lists for easy reference selected data from papers III<sup>17</sup> and VI<sup>6</sup> bearing on the present study.

**Acetolysis of Optically Active 3-endo-Methyl-2-exo-norbornyl *p*-Bromobenzenesulfonate.** Prepared from the same enantiomer of 3-endo-methyl-2-exo-norbornanol that gives (–)-1 ( $X = \text{OAc}$ ) on acetylation, the corresponding *p*-bromobenzenesulfonate (1,  $X = \text{OBs}$ ) solvolyzes in sodium acetate buffered acetic acid to give the same mixture of products already described in the racemic series.<sup>16</sup> Three of these acetates are isolated by preparative vapor chromatography with scrupulous precautions to avoid optical fractionation. The acetate of the starting 3-endo-methyl-2-norbornyl structure is isolated with the same sign and  $99 \pm 1\%$  of the magnitude of rotation as that prepared by direct acetylation of the alcohol used to prepare the active substrate 1,  $X = \text{OBs}$ . (–)-7-*anti*-Methyl-2-exo-norbornyl acetate (7), the configuration and absolute rotation of which are established in paper III,<sup>17</sup> is also isolated with complete preservation ( $101 \pm 1\%$ ) of optical purity. Finally, the formation of (–)-2-endo-methyl-2-exo-norbornyl acetate (3) with complete retention of optical purity is demonstrated by isolation of the corresponding (+)-tertiary alcohol after lithium aluminum hydride reduction of the solvolysis reaction mixture. The rotation to be expected of the tertiary alcohol can be calculated as follows. The unsaturated acid 8 [(–)-2-endo-methyl-2-exo-5-norbornenecarboxylic acid] of  $[\alpha]_D -41.4^\circ$  has been converted<sup>18</sup> to (–)-camphenilane of  $[\alpha]_D -8.20^\circ$ . In Scheme I, (+)-8 of  $[\alpha]_D +24.6^\circ$  gave (–)-3-OH of  $[\alpha]_D -4.22^\circ$  by the Baeyer–Villiger route (i), whereas (+)-8 of  $[\alpha]_D +32.1^\circ$  gave (–)-3-OH of  $[\alpha]_D -5.20^\circ$  by the deamination route (ii). Also, (–)-1,  $X = \text{OAc}$ ,  $[\alpha]_D -1.85^\circ$ , gave camphenilone (2) of  $[\alpha]_D +16.5^\circ$ , and 2 of  $[\alpha]_D +11.6^\circ$  gave camphenilane (6) of  $[\alpha]_D -2.20^\circ$ . Using the results of the Baeyer–Villiger route (i), the rotation expected for 3-OH derived from the *p*-bromobenzenesulfonate corresponding to (–)-1a,  $X = \text{OAc}$ , of  $[\alpha]_D -1.85^\circ$  is

$$[\alpha]_{\text{calcd}} = -4.22 \left( \frac{-41.4}{+24.6} \right) \left( \frac{-2.20}{-8.20} \right) \left( \frac{+16.5}{+11.6} \right) = +2.70^\circ$$

Using the data of the “deamination route” (ii)

$$[\alpha]_{\text{calcd}} = -5.20 \left( \frac{-41.4}{32.1} \right) \left( \frac{-2.20}{-8.20} \right) \left( \frac{+16.5}{+11.6} \right) = +2.56^\circ$$

If these figures are taken to represent the limits of experimental error, the observed value  $[\alpha]_D +2.64^\circ$  corresponds to  $100 \pm 3\%$  retention.

The configuration and optical purity of tertiary product (–)-3 show that it belongs entirely to the stereochemical series that results from direct *exo*-vicinal hydride shift in cation A. The simplicity of this reaction is in striking contrast to the behavior of the epimeric 3-*exo*-methyl cation C.<sup>8</sup>

The hydride shift that converts secondary cation A to tertiary cation A<sub>1</sub> is at least predominantly intramolecular. Solvolysis of 3-endo-methyl-2-exo-norbornyl *p*-bromobenzenesulfonate in acetic acid-*O-d* under the same conditions used in the optically active series produces an acetate mixture from which tertiary acetate 3 is isolated containing only 0.23 atom of deuterium per molecule. This small amount of incorporation results from a reaction of the product 3 after its formation, as control experiments show.<sup>8</sup> Thus, in processes that expose it only once, A<sub>1</sub> is formed by essentially completely intramolecular hydride shift. Re-formation of A<sub>1</sub>, even in buffered medium, permits incorporation of deuterium,<sup>8</sup> but, fortunately, racemization by 6,2 shift in A<sub>1</sub> is slow enough (see above) to be undetectable.

The 6,2 shifts that lead to the other solvolysis products from 1 ( $X = \text{OBs}$ )<sup>16</sup> are also entirely intramolecular. The total secondary acetate mixture incorporates only 0.0084 atom of deuterium per molecule.

The uniformly high optical purities of the products from the acetolysis of 1,  $X = \text{OBs}$ , demonstrate the absence of secondary–secondary hydride shift and of vicinal methyl shift in cation A, both of which are racemizing events. This allows the construction of Scheme II for use in a more detailed scrutiny of part of the over-all mechanism discussed in paper I.<sup>4</sup> The nomenclature of the cations follows that used there.<sup>4</sup> From the stereochemical results and distributions of products, it is now possible to deduce two important rate constant ratios in terms of Scheme II.

Scheme II

**Relative Rates of Vicinal (3,2) Hydride Shift and Solvent Capture.** Assume that the concentrations of all of the carbonium ion intermediates can be expressed by steady-state equations. It is known<sup>16</sup> that the con-

n of secondary ion A to its more stable hydride-1 tertiary isomer A<sub>1</sub><sup>18</sup> is essentially irreversible. optical purity (P) of product 3 or 1a (X = OAc) with 1a (X = OBs) is then given by eq 1 and 2. Significance of the rate constants is given in Scheme 1 for  $k'_6$ ,  $k'_{-6}$ , and  $k_6$  which refer respectively to forward and reverse rate constants for 6,2-hydride shift in cation A (and its enantiomer A<sub>2</sub>) and capture of the hydride-shifted cations C and B (and their enantiomers C<sub>1</sub> and B<sub>1</sub>). Rate constants  $k_6$  and  $k_7$  include solvent concentration terms. Bracketed terms of eq 1 represent steady-state concentrations.

$$k_{s,s} + k'_6 + k_{t,s} + k_1 + k_7 - k'_6 k'_{-6} / (k_6 + k_{-6}) = k_{ss}[A]/[A_2] \quad (1)$$

optical purity of 3 or 1a =  
 $(1 - k_{s,s}/v)/(1 + k_{s,s}/v) \quad (2)$

reaction (F) of the total acetate product represented by 3 is given by eq 3.

$$F = k_{t,s}/(v - k_{s,s}) \quad (3)$$

The manipulation of eq 2 and 3 gives the ratio of the migration of *exo* hydrogen from a tertiary to a secondary carbon ( $k_{t,s}$ ) to that from a secondary to a secondary carbon ( $k_{s,s}$ ) (eq 4).

$$k_{t,s}/k_{s,s} = (2P/1 - P)F \quad (4)$$

product distribution<sup>18</sup> gives F as 0.07. The value is essentially unity whether determined from the optical purity of 3 or from that of 1, X = OAc, but the latter is more accurate since it is obtained by direct comparison of the rotations of a single substance.  $P \geq 0.99$ ,  $k_{t,s}/k_{s,s}$  has a minimum value of 14. The ratio of  $k_{t,s}$  to the composite rate constant  $k_{sOH} + k_7$  measures the competition between tertiary-secondary hydride shift and solvent capture of ion A. It can be evaluated with the previously reported data<sup>18</sup> for the ratio 3:(1 + 7) as 0.074 in aqueous ethanol, 0.18 in aqueous dioxane, 0.115 in formic acid, and 0.115 in acetic acid. Thus,  $k_{sOH}/k_{s,s}$ , the competition between solvent capture and secondary-secondary hydride shift in A, is 14:0.115 or at least 122 in acetic acid at 0°. A factor this large would suffice to prevent formation of a detectable amount of 3,2-shifted product from norbornyl cation itself (2,3-<sup>14</sup>C-labeled). Usually, this ratio may be very much larger. As a starting rate, we may use 6,2-hydride shift, which is known<sup>12-16</sup> to be competitive with and hence of the same order of magnitude as solvent capture in many norbornyl systems. A direct comparison between 6,2-secondary-secondary 3,2 shift in norbornyl cation is available from the proton magnetic resonance spectrum in solvent SbF<sub>5</sub>-SO<sub>2</sub>ClF-SO<sub>2</sub> at -120°, which shows<sup>19</sup> that 6,2 shift is at least 8.8 powers of ten faster than 3,2 shift. If this rate ratio were largely due to a difference in activation enthalpy and if it persisted

in hydroxylic media, 6,2 shift would be faster than 3,2 shift under the solvolysis conditions (water or acetic acid solvent, 25-100°) by factors in the range  $4 \times 10^4$ – $3 \times 10^4$ . Thus, solvent capture should overwhelm secondary-secondary 3,2 shift by several orders of magnitude. Experimentally, no 3,2 shift was detected<sup>13,20a</sup> in the acetolysis of *exo*-norbornyl *p*-bromobenzenesulfonate-2,3-<sup>14</sup>C, but Lee and Lam later reported<sup>20b</sup> having found such a process in the acetolysis of the corresponding 2-tritio derivative. These authors interpreted<sup>20b</sup> their data in terms of 1-2% of C-3 tritio product. The total per cent contribution of 3,2 shift would have had to be in the range 7-10% to account for this,<sup>20b</sup> so that 3,2 shift and 6,2 shift, according to this interpretation, cannot differ very much in rate. Furthermore, 3,2 shift seems to be just detectable in formolysis of <sup>14</sup>C-labeled material,<sup>13,20,21</sup> although it is not clear whether the distribution there is completely kinetically controlled. If the reports of competitive 3,2 and 6,2 shifts in hydroxylic media are correct, one is forced to the conclusion that the relative and absolute magnitudes of these specific rates can vary by several powers of ten as a function of solvent. Since the rates observed by nmr techniques in nonhydroxylic media are being used as approximations to the rates under solvolytic conditions,<sup>22</sup> it would seem imperative that the discrepancy be resolved. The closely related matter of absolute rates of capture of the cations in solvolytic media is briefly discussed in the Appendix.

**Relative Rates of Transannular (6,2) Hydride Shift and Solvent Capture.** Estimates of these relative rates for the secondary-secondary case can be made from studies of isotope-position rearrangement in solvolyses of 2,3-<sup>14</sup>C-norbornyl derivatives<sup>13</sup> or from the more recent experiments in the 2-tritio-norbornyl series.<sup>20b</sup> The adjacent diagram (Scheme III) outlines the basis for

Scheme III

Only one resonance form of A<sub>1</sub> is shown here. The argument is essentially changed whether A<sub>1</sub> is considered to be a resonance hybrid of secondary nonclassical ion or a tertiary classical ion. We are concerned here or in the sequel with the distinction.

the calculations from the  $^{14}\text{C}$  data. Vicinal shift is assumed to be slow.<sup>13b</sup> Kinetic isotope effects in this type of marking are all secondary and are assumed to be small. The tritium-labeling data<sup>30b</sup> must be handled in a different manner, which is described in the Appendix. The total per cent rearrangement of isotope position is given by  $F_x(50) + F_y(50) + F_z(100)$ , where  $F_x$ ,  $F_y$ , and  $F_z$  are the fractions of product formed from cations X, Y, and Z. By symmetry, the steady-state concentrations of Y and Z are equal, and hence  $F_y = F_z$ . Thus, the total per cent rearrangement may be expressed as in eq 5.

$$F_x(50) + F_y(150) = \text{total \% rear} \quad (5)$$

But  $F_y = (1 - F_x)/2$ , so that eq 5 can be put in the form of eq 6. From the previously derived<sup>16</sup> relationships

$$F_x = 3 - \text{total \% rear}/25 \quad (6)$$

(eq 7 and 8), one obtains eq 9, which permits an experi-

$$F_x = (k_H + k_{\text{OH}})/(3k_H + k_{\text{OH}}) \quad (7)$$

$$F_y + F_z = 2k_H/(3k_H + k_{\text{OH}}) \quad (8)$$

$$k_H/k_{\text{OH}} = (1 - F_x)/(3F_x - 1) \quad (9)$$

mental evaluation of the competition between secondary-secondary 6,2-hydride shift and solvent capture of norbornyl cation. The corresponding competition ratio for a tertiary-secondary case is supplied by the product distribution<sup>16</sup> from 6-*endo*-methyl-2-norbornyl *p*-bromobenzenesulfonate (9). Table II summarizes these ratios.

An estimate of the effect of methyl substitution on the absolute rate of 6,2-hydride shift would bear upon the question of charge distribution in the transition state. Although such an estimate based on the data of Table II is at best a rough one, it seems worth making. One should first make some attempt to relate the hydride shift rates to a common solvent capture rate  $k_{\text{OH}}$ . It seems reasonable to assume<sup>16</sup> that  $k_{\text{OH}}$  would be roughly the same for attack at the favored position<sup>16</sup> (C-1) of the 6-methyl cation (D) as for attack on norbornyl cation. Since attack at C-2 of D is only about one-tenth as fast,<sup>16</sup>  $k_{\text{OH}}$  for D can be taken to be roughly one-half  $k_{\text{OH}}$  for norbornyl cation. The experimental  $k_H/k_{\text{OH}}$  values of Table II for the 6-methylnorbornyl cases are therefore divided by this statistical factor of 2.

Table II. Competition Ratios (6,2-Hydride Shift *vs.* Solvent Capture) for Secondary-Secondary (s,s) and Tertiary-Secondary (t,s) Systems

Structure	Type of shift	Solvent	Temp, °C	$k_H/k_{\text{OH}}$
Norbornyl	s,s	Aq acetone	45	0.12
Norbornyl	s,s	HOAc	45	0.27
6-Methylnorbornyl	t,s	Aq EtOH	100	0.92 (0.46)
6-Methylnorbornyl	t,s	HOAc	100	2.45 (1.22)

\* The value in parentheses is an estimate derived from a statistical correction of the experimental value (see text).

If 6,2-hydride shift at both the ion-pair and separation stages occurred in the norbornyl cation<sup>23</sup> but in 6-methylnorbornyl, the norbornyl ratios of Tab derived upon the assumption of a "single pass" petition, would be too high. It is difficult to guess much correction should be applied for this,<sup>23</sup> but were large, the observed total per cent rearrange figures would have approached the "equilibrium" value of 66.7%. This is not found to be the case. The change in temperature (45–100°) between the norbornyl and 6-methylnorbornyl experiments might change the  $k_H/k_{\text{OH}}$  ratio in acetic acid by a factor of about 2 (see Appendix).

One concludes that the enhancement of the rate of 6,2-hydride shift by methyl substitution is a factor between about 5 and about 15 in acetic acid. This effect on the removal of "hydride ion" from the transition state distance contrasts strongly with the enormous change produced by methyl substitution on  $\text{S}_{\text{N}}1$  solvolyses,<sup>24</sup> where achievement of the transition state involves stretching a halogen-carbon bond. In reactions of bromides, for example, alteration of secondary structure (isopropyl) to tertiary (*t*-butyl) enhances the solvolysis rate by factors ranging between  $10^3$  and  $10^5$ . Although ground-state energy differences cannot be ignored, it seems likely that a major cause of the observed weakening of the methyl substituent has to do with charge distribution in the transition state. The transition state for halide solvolysis would have a substantial amount of positive charge localized at the reaction site, and its energy would, therefore, be very responsive to alkyl substitution, but the transition state for 6,2-hydride shift if it resembles an endo-cyclopropane,<sup>25</sup> consistent with the *endo-endo* geometry of the process,<sup>26</sup> might be expected<sup>27</sup> to have relatively little positive charge at the migration origin (C-6) or terminus (C-2). Much of the charge might well be localized on the migrating hy-

(c) As has been pointed out,<sup>23a</sup> the possibility cannot be dismissed that substituent change the 6,2-shift intermediate or transition state from hypothetically face protonated in simple norbornyl cation to edge protonated (stereochemically equivalent leading to an *endo-endo* process) in substituted examples actually studied.<sup>23a,b</sup> However, this is not the content of the statement<sup>23d</sup> that in the substituted cases, "either the face-protonated or the edge-protonated intermediate could produce the experimental result." In the case of the 1-methyl-7-carboxynorbornyl cation, a single face-protonated intermediate of nominal *t*-symmetry was experimentally excluded.<sup>23a</sup> (d) C. J. Collins and M. Benjamin, *J. as extended Hückel calculations suggest is the case cyclo- $C_3H_7^+$  itself.<sup>27</sup>

## Experimental Section

**Optical Activation of 3-endo-Methyl-2-exo-norbornyl Acetate.** A solution of 600 g of the racemic acid phthalate<sup>10</sup> in acetone was brought to boiling on the steam bath and treated with an equimolar amount of ephedrine. After a short while the mixture was homogeneous; it was cooled to room temperature and allowed to stand overnight, after which time a large amount of the salt had crystallized from the solution. The white crystals collected on a Büchner funnel and recrystallized ten times in acetone, yielding 165 g of salt in the head crop. A 50.0-g quantity of this material was stirred rapidly with about 200 g of crushed ice, 30 ml of 35% aqueous HCl, and 75 ml of ether. When the mixture was no longer visible in the mixture, the phases were separated and the aqueous layer was extracted twice more with ether. The combined ether fractions were washed with 5% hydrochloric acid, water, and brine, and dried over sodium sulfate. They were then concentrated and the solvent was evaporated at the aspirator, leaving a quantitative yield of optically active acid phthalate, which had a specific rotation of  $[\alpha]^{25}_D - 3.98^\circ$  ( $CHCl_3$ ).

Optically active acid phthalate was mixed with 40 ml of 15% sodium hydroxide and steam distilled. Optically active 3-endo-methyl-2-exo-norborneol, **1a**,  $X = OH$ , distilled over completely in 10 min and crystallized in the aqueous distillate. To

facilitate extraction of the distillate with pentane, after saturation of the aqueous phase with salt. The combined pentane extracts were washed with 1% hydrochloric acid and brine and dried over sodium sulfate. The pentane solution was then concentrated to a manageable volume, but the alcohol was not allowed to crystallize. An aliquot was removed and concentrated to dryness at the aspirator, and an infrared spectrum taken. It was identical with that of the pure racemic sample.<sup>10</sup> A second aliquot was removed and converted to optically active 3-endo-methyl-2-exo-norbornyl acetate, which had an infrared spectrum and retention time on vpc identical with that of the racemic sample. Analysis by capillary vpc showed it to be 99% homogeneous. The rotation was  $[\alpha]^{25}_D - 1.85^\circ$  (absolute alcohol).

**Resolution of Optically Active 3-endo-Methyl-2-exo-norbornyl Acetate ((-)-**1a**,  $X = OAc$ ) with (+)-Camphenilone (2).** The mixture of 3-methyl-2-norbornanones derived from the above active acetate,  $[\alpha]^{25}_D - 1.85^\circ$ , has been described elsewhere.<sup>17</sup> A portion (10 g) of the mixed ketones was dissolved in 5 ml of dry dimethyl sulfoxide (previously distilled from lithium aluminum hydride). The solution was transferred to a round-bottomed flask and the flask was flamed out under a stream of nitrogen, cooled, and charged with 1.8 g of potassium hydroxide and 40 ml of dry dimethyl sulfoxide. The ketone solution was then added to the flask dropwise from a pressure-equalizing funnel, while the entire system was protected with a nitrogen blanket. Upon the addition the cloudy, off-white solution turned yellow

and after the mixture had been stirred for 20 min, 15 ml of freshly distilled methyl iodide was added dropwise while stirring was continued. The cloudiness and color disappeared immediately, and the mixture was allowed to stir for 2 hr at room temperature. The mixture was then added and the mixture was extracted four times with pentane. The combined pentane extracts were washed repeatedly with water and once with saturated brine, and dried over sodium sulfate. Decantation and evaporation left a greenish oil containing 15% 3-exo-methyl-2-norbornanone, 5% 3-endo-methyl-2-norbornanone, 60% camphenilone (2), and the rest low-boiling compounds. After distillation bulb to bulb, the distillate was chromatographed on column D-1. By this procedure the optically active camphenilone could be obtained in better than 99.0% purity. It had a specific rotation of  $[\alpha]^{25}_D + 16.5^\circ$  (benzene).

**Inversion of (+)-Camphenilone to (-)-Camphenilane.**<sup>1</sup> A sample of optically active camphenilone obtained from Light and Co. had a specific rotation of  $[\alpha]^{25}_D + 11.6^\circ$  ( $CHCl_3$ ) and weighing 1.0 g was dissolved in 10 ml of 95% ethanol. Semicarbazide hydrochloride (0.9 g) and sodium acetate (1.1 g dissolved in 5 ml of water) were added, and the resulting mixture was heated at reflux for 4 hr on the steam bath with a water condenser. The semicarbazone separated as white crystals on cooling; it was extracted with three portions of  $CHCl_3$ , the combined organic extracts were washed with saturated sodium chloride and dried over magnesium sulfate. The solution was filtered and an aliquot was taken for an infrared spectrum. The spectrum showed the expected N-H (2.9, 3.0  $\mu$ ) and C=O

(5.92  $\mu$ ) bands, and a complete absence of C=O absorption (5.72  $\mu$ ). The solution was therefore concentrated to dryness at the aspirator and all the product (5.5 g, 97% yield) was removed and mixed with 4.5 g of pulverized KOH. This solid mixture was placed in a 100-ml, round-bottomed flask and shaken to ensure homogeneity. A short-path distillation apparatus was attached, and the flask was heated in a Woods' metal bath from 170 to 260°. As the temperature rose, the solid fused and bubbled and a two-phase mixture collected in the receiver. When the distillation was complete, the material in the pot had solidified to a tan mass.

The organic layer was drawn off the top of the distillate with a pipet, a little pentane was added to the aqueous phase, and the pentane layer was drawn off and combined with the first fraction. After a small amount of magnesium sulfate was added to the organic mixture, it was centrifuged and the liquid was separated from the magnesium sulfate. The solid was washed with pentane and the pentane was combined with the rest of the hydrocarbon. As an infrared spectrum of this mixture showed a small C=O band, about 0.060 g of lithium aluminum hydride was added and the material was distilled bulb to bulb at atmospheric pressure. The hydrocarbon (2.5 g, 72% yield) came over as a clear liquid, solidifying in the Dry Ice trap. Chromatography on column D-1 at 135° gave camphenilane (6), which was again distilled bulb to bulb and thus obtained better than 99.0% pure by capillary vpc. Its specific rotation was  $[\alpha]^{25}_D - 2.20^\circ$  (benzene), and its infrared spectrum was identical with that of a racemic sample.<sup>18</sup>

**Solvolysis of Racemic 3-endo-Methyl-2-exo-norbornyl p-Bromobenzenesulfonate (1a,  $X = OBr$ ).** A 0.1 M solution of sodium acetate in acetic acid was heated to thermal equilibrium in an oil bath at 95°. With rapid stirring, a suspension of 12.3 g of the sulfonate<sup>10</sup> in another 50 ml of buffer solution was then added dropwise to the hot solution. The resulting mixture was stirred at this temperature for 15 min, after which time it was allowed to cool to room temperature and poured onto pentane and cracked ice. The phases were separated, the water phase was extracted twice more with pentane, and the combined organic layers were washed with water, saturated sodium bicarbonate solution, and brine, and dried over sodium sulfate. The solution was decanted, and the pentane was distilled away carefully with a Vigreux column, leaving a greenish, sweet-smelling oil. Bulb-to-bulb distillation of this material at 15 mm gave 5.0 g (83%) of acetates as a water-white oil. An analysis of this material by capillary vpc showed that it contained several products, whose identities and relative proportions are given elsewhere.<sup>18</sup>

In another experiment, 0.9 g of the sulfonate was solvolyzed under the same conditions, but for a longer period of time. Aliquots were withdrawn periodically and worked up individually as above. Analysis of these aliquots by vpc indicated that the solvolysis was essentially complete after 5 min at 95°, and the relative proportions of the products remained constant for several hours afterward. At very long reaction times (greater than 4 or 5 hr) small amounts of other products, 1-methyl-2-exo-norbornyl acetate and 2-exo-methyl-2-endo-norbornyl acetate, could be detected.

A solvolysis of 3-endo-methyl-2-exo-norbornyl p-toluenesulfonate was carried out in a manner identical with that of the p-bromobenzenesulfonate solvolysis. The product pattern, analyzed by capillary vpc after work-up, was identical with that from the p-bromobenzenesulfonate.

**Solvolysis of 1a in O-Deuterioacetic Acid.** The procedure described for solvolysis of 1a,  $X = OBr$ , and isolation of tertiary alcohol 3-OH in the optically active series was repeated on a sample of racemic p-bromobenzenesulfonate, except that O-deuterioacetic acid was employed as solvent. Falling drop analysis on 3-OH showed it to contain 1.6 atoms % excess deuterium (0.23 atom of deuterium per molecule), and analysis of the remainder of the alcohols showed the mixture to contain 0.06 atom % excess deuterium (0.0084 atom of deuterium per molecule).

**Solvolysis of Optically Active 1a,  $X = OBr$ .** An aliquot of the same pentane solution of 3-endo-methyl-2-exo-norbornyl acetate,  $[\alpha]^{25}_D - 1.85^\circ$ , contained about 9 g of the alcohol. This was converted to the p-bromobenzenesulfonate in a procedure identical with that used to prepare the racemic derivative.<sup>10</sup> The material obtained was identical in spectral properties with the racemic sulfonate, except that the infrared showed the presence of a small amount of residual starting alcohol. A preparative-scale solvolysis on 20.6 g of the optically active sulfonate was carried out under the same conditions as the racemic analog,<sup>18</sup> and 7.6 g (75%) of acetates was obtained from the reaction. The entire mixture was reduced to alcohols with lithium aluminum hydride, and 2-endo-

methyl-2-*exo*-norborneol (3) was separated from the other products on vpc column B at 135° after bulb-to-bulb distillation of the mixture at 13 mm. The tertiary alcohol was collected as white needles, pure by capillary vpc. After bulb-to-bulb distillation, it had a specific rotation of  $[\alpha]^{25}_D +2.64^\circ$  (CHCl<sub>3</sub>). Its infrared spectrum was identical with that of a racemic sample.

The remainder of the solvolysis material was collected as a semi-solid and reconverted to acetates in the usual way. The two major products, 3-*endo*-methyl-2-*exo*-norbornyl acetate (1a, X = OAc) and 7-*anti*-methyl-2-*exo*-norbornyl acetate (7), were separated from the rest of the mixture on column E at 175°. Both were recycled on the same column to give acetate 1a in better than 99.0% purity and 7 in 98.0% purity. Acetate 1a obtained in this way was identical in infrared spectrum and capillary vpc retention time with authentic 1a. It was found to have specific rotation  $[\alpha]^{25}_D -1.83^\circ$  (absolute ethanol) and is thus formed with  $99 \pm 1\%$  retention of configuration. The sample of 7 obtained from this solvolysis was identical in infrared spectrum and retention time on vpc with material obtained from the deamination of 3-*endo*-methyl-2-*exo*-norbornylamine hydrochloride<sup>14</sup> and had a specific rotation of  $[\alpha]^{25}_D -3.19^\circ$  (95% ethanol).

**Scheme I. Correlation of 2-*endo*-Methyl-5-norbornene-2-*exo*-carboxylic Acid (8) with 2-*endo*-Methyl-2-*exo*-norbornanol (3-OH).** (I) Baeyer-Villiger Route, Racemic Series. Hydrogenation of pure racemic 8,<sup>28,29</sup> conversion to the acid chloride, and reaction of the latter compound with dimethylcadmium were carried out in the manner described<sup>10</sup> for similar transformations. Racemic 2-*endo*-methyl-2-*exo*-acetylnorbornane was a liquid, bp 95–98° (25 mm),  $n^{25}_D 1.4759$ .

*Anal.* Calcd for C<sub>10</sub>H<sub>18</sub>O: C, 78.89; H, 10.60. Found: C, 78.63; H, 10.66.

The 2,4-dinitrophenylhydrazone was recrystallized from ethanol and had mp 155.5–156°.

*Anal.* Calcd for C<sub>14</sub>H<sub>20</sub>O<sub>4</sub>N<sub>2</sub>: C, 57.82; H, 6.07. Found: C, 57.73; H, 6.19.

The racemic ketone reacted with perbenzoic acid in the usual manner<sup>10</sup> to give 2-*endo*-methyl-2-*exo*-norbornyl acetate.

**Optically Active Series.** A sample of 8 obtained by resolution<sup>28</sup> had  $[\alpha]_D +24.6^\circ$  (95% ethanol). It was hydrogenated over platinum oxide in methanol to the saturated acid which then was converted to the ketone as in the racemic series. The ketone had  $[\alpha]_D +9.25^\circ$  (CHCl<sub>3</sub>),  $n^{25}_D 1.4751$ , and was homogeneous by vpc. Its infrared spectrum was identical with that of the racemate.

Oxidation with perbenzoic acid as in the racemic series followed by reduction with lithium aluminum hydride gave a mixture of alcohols which was purified by preparative vapor chromatography on column C to give pure 2-*endo*-methyl-2-*exo*-norbornanol (3-OH),  $[\alpha]_D -4.22^\circ$  (CCl<sub>4</sub>). This material had mp 84–85°. It was homogeneous on column L, and its infrared spectrum was identical with that of the racemate.

**Scheme I. (II) Deamination Route.** A sample of 2-*endo*-methyl-5-norbornene-2-*exo*-carboxylic acid (8) obtained by resolution<sup>28</sup> had  $[\alpha]_D +32.1^\circ$  (95% ethanol). It was hydrogenated and treated with thionyl chloride to give the corresponding saturated acid chloride. This material was dissolved in dry ether and treated with dry ammonia gas. Filtration of the solid, concentration of the filtrate, washing of the combined solids with water, extraction of the water wash with ether, evaporation of the ether, and drying of the combined solid gave 98.4% of the amide,  $[\alpha]_D +5.65^\circ$  (methanol).<sup>30</sup> This material was subjected to the Hofmann rearrangement under the conditions reported by Sauers<sup>31</sup> in the racemic series. The resulting amine hydrochloride had an infrared spectrum identical with that of the racemate (kindly supplied by Professor Sauers<sup>31</sup>).

The amine hydrochloride (3.8 g) in a mixture of 10 ml of water and 2.5 ml of acetic acid was treated with a solution of 2.5 g of sodium nitrite in 8 ml of water. The reaction mixture was allowed to stand 3 hr, poured into 150 ml of water, and extracted with pentane. Drying, evaporation of the pentane, lithium aluminum hydride reduction, reacetylation, distillation, and reduction gave 2-*endo*-methyl-2-*exo*-norbornanol,  $[\alpha]_D -5.20^\circ$  (CCl<sub>4</sub>).

**Scheme I (III).** Asymmetric hydroboration<sup>32</sup> of norbornene with

diisopinocampheylborane (prepared from  $\alpha$ -pinene of [ $\alpha$ ]<sub>D</sub> -42.7° [c 2.3, absolute EtOH], kindly supplied by Dr. H. Enos of Hercules Powder Co.) and acetylation of the crude alcohol obtained after oxidation gave (–)-*exo*-2-norbornyl acetate,  $\alpha -3.31^\circ$  (neat, 1 dm), after distillation through a spinning-band column. This material contained less than 5% of the *endo* isomer as estimated by vpc (column N) of the alcohol derived from it by lithium aluminum hydride reduction. Jones oxidation<sup>33</sup> gave 2-norbornanone,  $[\alpha]_D -7.95^\circ$  (chloroform), which was homogeneous (columns L and N).

Methyl Grignard reagent was prepared in 150 ml of ether in a 1-l., three-necked flask from 6.90 g (0.28 g-atom) of magnesium turnings and 15.9 ml (at 0°) of methyl bromide (0.29 mole). To this mixture was added a solution of 23.5 g (0.213 mole) of norbornanone,  $[\alpha]_D -7.95^\circ$  (chloroform), in 100 ml of ether over a 20-min period. The light tan mixture was stirred for 1 hr at room temperature. The excess reagent was destroyed with a saturated solution of ammonium chloride. The solution and salts were cooled to 0° and almost all the precipitate was dissolved with 2 N hydrochloric acid; the solution was still alkaline as evidenced by the odor of ammonia.

The clear ether layer was separated from the aqueous phase and the latter extracted four times with pentane to give a combined organic solution of ca. 650 ml which was twice washed with saturated brine and dried over sodium sulfate. The solvent was carefully fractionated off, to give a slightly yellow oil.

The crude oil was distilled bulb to bulb at 95° (ca. 25 mm), to yield a white crystalline solid; the infrared spectrum and retention times on vpc were identical with those of a racemic sample of 2-*exo*-methyl-2-*endo*-norbornanol prepared by the method of Toivonen.<sup>12b</sup> The yield was 25.5 g (95%). A representative sample was taken from the molten alcohol:  $[\alpha]^{25}_D -6.45 \pm 0.09^\circ$ ;  $[\alpha]^{25}_{365} -17.41 \pm 0.05^\circ$  (c 4.3, chloroform), average values and standard deviations given for four determinations.

The above alcohol was acetylated with excess acetic anhydride and pyridine at 100° for 24 hr to give, after the usual work-up and distillation, a 100% yield of the acetate, whose infrared spectrum and vpc retention times on vpc were identical with those of the authentic, racemic material. Capillary vpc on column N indicated the presence of ca. 0.05% *t-exo* acetate, rotation  $[\alpha]^{25}_D -12.09 \pm 0.07^\circ$ ,  $[\alpha]^{25}_{365} -36.84 \pm 0.08^\circ$  (c 6–7.8, chloroform). Treatment with lithium aluminum hydride regenerated the starting alcohol with unchanged rotation.

**2-*endo*-Methyl-2-*exo*-norbornanol [(+)-3-OH].** A homogeneous sample of 3.00 g of the above optically active 2-*exo*-methyl-2-*endo*-norbornanol was stirred with concentrated hydrochloric acid for 2 hr at room temperature. The chloride was extracted with pentane, washed with brine, and evaporated to give a residue which was homogeneous on columns L and N except for traces of pentane. The crude chloride was stirred at 95° with 35 ml of 1 N sodium hydroxide for 4 days and extracted with pentane. Washing with brine, drying over sodium sulfate, removal of solvent, and sublimation gave 2.36 g (80%) of (+)-3-OH, infrared spectrum and vpc retention time identical with those of an authentic racemic sample.<sup>12b</sup> The rotations were  $[\alpha]_D +2.78 \pm 0.006^\circ$ ;  $[\alpha]_{365} +8.38 \pm 0.02^\circ$  (c 5.0–5.3, chloroform).

The corresponding acetate (–)-3-OAc prepared in 94% yield from this sample had  $[\alpha]_D -1.01 \pm 0.03^\circ$ ;  $[\alpha]_{365} -3.36 \pm 0.01^\circ$  (c 5.2–5.4, chloroform), and contained 0.75% of the epimeric acetate. Lithium aluminum hydride regenerated (+)-3-OH with unchanged rotation which contained no 1-methyl-2-*exo*-norbornanol (0.05% could have been detected, column L).

By a previously described procedure,<sup>34</sup> 2-*exo*-methyl-2-*endo*-norbornanol,  $[\alpha]_D -6.45^\circ$  (chloroform), was converted to 1-methyl-2-*exo*-norbornyl acetate,  $[\alpha]_D +9.29 \pm 0.03^\circ$ ;  $[\alpha]_{365} +28.0 \pm 0.005^\circ$  (c 5.2–5.4, chloroform), which was reduced with lithium aluminum hydride to 1-methyl-2-*exo*-norbornanol,  $[\alpha]_D +0.21 \pm 0.02^\circ$ ;  $[\alpha]_{365} -2.11 \pm 0.02^\circ$  (c 5.8–5.9, chloroform). Reacetylation gave back the acetate with unchanged rotation.

## Appendix

**6,2-Hydride Shifts in the 2-Norbornyl-2-*t* System.** The threefold symmetry properties associated with 6,2-hydride shifts in 2-norbornyl-2,3-<sup>14</sup>C cations are perturbed in the 2-norbornyl-2-*t* analogs. In the 2,3-<sup>14</sup>C case (Scheme III), three successive transannular shifts in a given direction suffice to complete the symmetry operation by which the starting cation is trans-

formed into itself. Although the 2-*t* case has also been discussed as if it were threefold symmetric,<sup>20b</sup> this approach is not really justifiable. The number of successive transannular hydride shifts needed to complete the symmetry operation depends upon the stereochemistry of these shifts. If, as seems likely,<sup>26</sup> these are constrained to be *endo-endo*, four successive transannular shifts are required to complete a cycle (Scheme IV). The competition ratio  $k_{\text{OH}}/k_{\text{H}}$  can be calculated

Scheme IV

from experimental data by means of eq 10, which is derived by treating all of the cationic intermediates by steady-state methods, assuming no isotope effect ( $k_{\text{H}} = k_{\text{T}}$ ).

$$R_{\text{T}} = (F_{\text{M}} + F_{\text{N}})/(F_{\text{K}} + F_{\text{L}}) = \frac{4 + (k_{\text{OH}}/k_{\text{H}})}{4 + 5(k_{\text{OH}}/k_{\text{H}}) + (k_{\text{OH}}/k_{\text{H}})^2} \quad (10)$$

The quantities  $F_{\text{M}}$ ,  $F_{\text{N}}$ ,  $F_{\text{K}}$ , and  $F_{\text{L}}$  represent the fractions of product formed from each of the four cations, and the quantity  $R_{\text{T}}$  is evaluable from the experimental ratio of 5,6-tritiated to 5,6-untritiated product, these two ring positions being inseparable in the degradation scheme. Solution of the quadratic and rejection of the physically insignificant negative root give the desired ratio  $k_{\text{OH}}/k_{\text{H}}$  (eq 11).

$$k_{\text{OH}}/k_{\text{H}} = \frac{1 - 5R_{\text{T}} \pm (9R_{\text{T}}^2 + 6R_{\text{T}} + 1)^{1/2}}{2R_{\text{T}}} = (1/R_{\text{T}}) - 1 \quad (11)$$

A cubic relationship (eq 12) is derived from the alternative extreme assumption of a large isotope effect ( $k_{\text{T}} = 0$ ).

$$R_{\text{T}}(k_{\text{OH}}/k_{\text{H}})^3 + (5R_{\text{T}} - 1)(k_{\text{OH}}/k_{\text{H}})^2 + (6R_{\text{T}} - 4)(k_{\text{OH}}/k_{\text{H}}) + 2(R_{\text{T}} - 1) = 0 \quad (12)$$

The ratio  $R_{\text{C}}$  of 5,6-labeled to 5,6-unlabeled product in the case of 2,3-<sup>14</sup>C starting material is readily derived from eq 7 and 8 as

$$k_{\text{OH}}/k_{\text{H}} = (1/R_{\text{C}}) - 2 \quad (13)$$

As eq 11, 12, and 13 show, the product distributions from 2,3-<sup>14</sup>C and 2-*t* starting materials are different functions of the rate constants in question, and the apparent correspondences noted<sup>20b</sup> between the two experiments in terms of "per cent contributions" of C-1, C-2 and C-1, C-2, C-3 equating processes are purely fortuitous. If the same rate constants apply to the two systems, eq 11, 12, and 13 show that, in principle, these "per cent contributions" cannot be the same. Expressed another way, the number of sequential steps required to achieve a given "per cent contribution" differs in the two cases. The proper cross-check is made *via* the rate constants. Thus, from the tritium experiments<sup>20b</sup> and eq 11 one calculates  $k_{\text{OH}}/k_{\text{H}} = 2.88$  in acetic acid at 45°. Using this value and eq 7, 8, and 13, one can calculate  $R_{\text{C}}$  and the distribution to be expected in the <sup>14</sup>C experiment under the same conditions: C-5, C-6, 17.0%; C-2, C-3, 41.5%; C-1, C-4, 20.8%; and C-7, 20.8%. This is in quite good agreement with the experimental values of 15, 40, 23, and 22%. Conversely, one can calculate  $R_{\text{T}}$  from eq 10 and the <sup>14</sup>C data, using the value 3.67 for  $k_{\text{OH}}/k_{\text{H}}$  obtained from eq 13. This leads to a calculated distribution of 17.6% of tritium at C-5, C-6, which is to be compared with the experimental value<sup>20b</sup> of 20.5%. Although the ratio  $k_{\text{OH}}/k_{\text{H}}$  determined from the tritium data is about 20% lower than the <sup>14</sup>C value, the distributions calculated in the cross-checks are rather insensitive to the discrepancy. The alternative assumption (eq 12) of a large isotope effect in the tritium experiments leads to  $k_{\text{OH}}/k_{\text{H}} = 2.7$ .

**The Temperature Effect on the Competition Ratio. An Estimate of the Minimum Activation Energy for the Capture of Norbornyl Cation.** From the  $k_{\text{OH}}/k_{\text{H}}$  ratios of 2.88 at 45° and 1.76 at 25°, derived from the tritium-labeling data<sup>20b</sup> and eq 11, one can calculate the Arrhenius activation energy difference between the processes of pseudo-unimolecular capture of norbornyl cation by the medium (solvent and/or lyate ion) and 6,2-hydride shift. Solvent capture has the higher activation energy by 4.65 kcal/mole. The  $k_{\text{OH}}/k_{\text{H}}$  ratio at 100° is calculated on this basis to be 8.5. The calculation assumes that the observed temperature effect on the tritium distribution is not the result of a temperature-dependent isotope effect.

To the extent that the tritium data (which cover only a narrow temperature range) may be relied upon, the figure 4.65 kcal/mole represents the first estimate of the minimum value of the activation energy for capture of a norbornyl cation in solution. Since this energy is of extreme importance in present discussions of carbonium ion behavior, its confirmation or revision by further experiment would be valuable.

# The Chemistry of Methylnorbornyl Cations. VI. The Stereochemistry of Vicinal Hydride Shift. Evidence for the Nonclassical Structure of 3-Methyl-2-norbornyl Cations<sup>1</sup>

Received October 31, 1966

**Abstract:** The 3-*exo*-methyl-2-norbornyl cation scrupulously avoids rearrangement to the 2-methyl-2-norbornyl cation by *endo*-3,2-hydride shift, despite the large thermodynamic driving force of the reaction. Instead, it takes a more circuitous route involving preliminary 6,2-hydride shift to the 7-*anti*-methyl-2-norbornyl-3-*endo*-methyl-2-norbornyl system, which then suffers *exo*-3,2-hydride shift. The mechanism is elucidated with optically active reactants, since the competing paths lead to enantiomeric forms of 2-methyl-2-norbornyl product. The more circuitous path involving *exo*-3,2 shift is at least 100 times as efficient as the direct one relative to solvent capture and 6,2 shift. Comparison with the results in the 3-*endo*-methyl series shows that the preference for *exo*-3,2 shift inheres in a faster rate for this process rather than in extraneous factors proposed for other systems. Pinacolic rearrangement of 3-*endo*-methyl-2,3-*exo*-norbornanediol gives exclusively 3-*endo*-methyl-2-norbornanone. A number of other examples of vicinal shifts reported in the literature are examined, and the possibility of an alternative mechanism for the longifolene-isolongifolene rearrangement is pointed out. The extension of simple quantum mechanical arguments from primitive three-center displacements to four- and five-center openings of mesomeric bridges is discussed. The experimental findings are fully in accord with a nonclassical structure for 3-methyl-2-norbornyl cation.

One of the characteristic features of norbornyl cation chemistry is the highly stereospecific capture of external nucleophiles from the *exo* direction, even when *endo* attack is sterically about as favorable or more so. This behavior was<sup>4</sup> and still is<sup>5,6</sup> one of the major reasons for assigning nonclassical structures to the product-forming intermediates in such systems. A reasonable corollary of the nonclassical cation hypothesis suggests that *internal* nucleophiles, such as the migrating vicinal

groups in Nametkin rearrangements, might also show a large *exo* preference.<sup>5,7-9</sup> The present paper reports a test that confirms this idea.

The formolysis of *syn*-7-methyl-2-*exo*-norbornyl acid phthalate (1) had been reported<sup>10</sup> to give 5-*exo*-methyl-2-*exo*- (2) and 1-methyl-2-*exo*- (3) norbornyl formates. The latter product was of particular interest, since the mechanism proposed<sup>10</sup> for its formation (Scheme I)

Rees in "Organic Reaction Mechanisms, 1965," Interscience Publishers, Inc., London, 1966, p 14, ascribe to one of us<sup>5a</sup> the view that in reactions of norbornyl derivatives, "kinetics alone give no information on the structure of the cationic intermediate" and conclude that adoption of this view necessitates abandonment of the *exo:endo* product ratio as a criterion also. However, the quoted passage<sup>5a</sup> is irrelevant, since it refers to an outline of the complex kinetic problems of hydrogen chloride catalysis of the camphene hydrochloride-isobornyl chloride rearrangement, not to the question of *exo:endo* solvolysis rate comparisons. Our position on the connection between solvolysis rate and cation structure is expressed in the introduction to an extensive discussion of the matter: "Mesomerism stabilizes a bridged cationic intermediate relative to the corresponding 'classical' carbonium ion...the transition state...benefits energetically from similar mesomerism; it is therefore expected that a solvolysis in which bridging and heterolysis occur simultaneously will be accelerated relative to some standard solvolysis lacking such a feature."<sup>5d</sup> (c) Reference 5a, p 118. ed an *endo*-vicinal hydride shift in the cationic ediate  $\text{C}_1$ ,<sup>11</sup> which violates the stereoelectronically ated<sup>6,7-9</sup> prohibition. An alternative but more ex mechanism (Scheme II) employing only *exo*- shifts is possible in principle, however.<sup>5</sup> This is a preliminary 6,2-hydride shift converting  $\text{C}_1$  to cation  $\text{A}_2$ , followed by an *exo*-vicinal 3,2- shift to produce cation  $\text{C}_2$ , which is enantiomeric with  $\text{A}_1$ . The mechanisms are clearly distinguishable in the optically active series once the relative configurations of the starting material and product are shed.

a number of reasons, it is preferable to modify the form of the problem, first by entrance to the cationic ion scheme (see paper I<sup>12</sup>) at  $\text{C}_1$  via a 3-*exo*-1 (4) rather than a 7-*syn*-methyl (1) precursor, and second by capture of the rearranged tertiary-second-order cation ( $\text{A}_1$  or  $\text{C}_2$ ) as tertiary product (5a or 5b) rather than secondary (3a or 3b). The first change is made by expediency, synthetic routes to optically active 1 and configurational correlation with 3 or 5 being active and/or difficult. The second is a response to earlier experience. Secondary product, the 1-methyl-norbornyl ester (3), is formed in appreciable amounts from either 1 or 4 only under conditions of negligible carbonium ion formation, that is, when the material accumulates during formolysis or acetolysis in the absence of an added buffer. Under these conditions, there is danger of racemization by 6,2-hydride shift and/or reversible formation of 1-methylcyclohexene,<sup>13</sup> and in fact, attempted acetolysis of 4 in the absence of sodium acetate leads to completely racemic 3. In the presence of sodium acetate as buffer, optical activity is preserved, but the kinetically controlled product mixture contains only 2.3% of the desired tertiary ester 5a or 5b. Despite the experimentally

uninviting prospect of dealing with such a small amount of material, it was nevertheless clear that this product was of theoretical significance and did not represent a minor side path, since its Wagner-Meerwein relative 3 is a major product under reversible conditions. The low yield of 5a or 5b under kinetically controlled conditions results merely from irreversible capture of the bulk of the material at earlier points in the complex mechanism of the rearrangement. Since control experiments show that tertiary product 5a or 5b is not formed from the other acetates under the solvolysis conditions, this material represents carbonium ions that elude such capture.

**Stereochemical Correlations.** A distinction between the mechanisms involving *endo*-<sup>10</sup> and *exo*-hydride<sup>5</sup> shifts thus rests upon the configurational correlation of 3-*exo*-methyl-2-*endo*-norbornyl starting material (4) and 2-*endo*-methyl-2-*exo*-norbornyl product (5a or 5b).

(+)-3-*exo*-Methyl-2-*endo*-norborneol (4, X = OH) is prepared *via* the "acid  $\rightarrow$  acetate" sequence from (+)-3-*exo*-methyl-2-*endo*-norbornanecarboxylic acid<sup>14</sup> (4, X = CO<sub>2</sub>H), the acid chloride (4, X = COCl), and the methyl ketone (4, X = COCH<sub>3</sub>), Bayer-Villiger oxidation of the latter to the acetate (4, X = OAc), and lithium aluminum hydride cleavage. The active acid (4, X = CO<sub>2</sub>H) is derived by hydrogenation of the unsaturated acid 6,<sup>14</sup> which is readily optically activated by fractional crystallization of the quinidine salt.

To minimize the accumulation of errors that inevitably accompanies a rotational correlation using two different relay compounds, it is desirable to correlate starting alcohol 4 (X = OH) with camphenilone (7), the same

The nomenclature of the cationic intermediates is that given in I<sup>12</sup> and retained throughout this series.

2. A. Berson, J. S. Wallia, A. Remanick, S. Suzuki, P. Reynolds, and D. Willner, *ibid.*, **83**, 3986 (1961).

(14) The racemic substance is reported by G. Komppa and S. Beckmann, *Ann.*, **523**, 68 (1936).

substance that had already served<sup>15</sup> as reference in the correlation of product alcohol 5a or 5b. This is accomplished by oxidation and methylation of (+)-4 (X = OH),  $[\alpha]_D +14.4^\circ$  (carbon tetrachloride), to (+)-7,  $[\alpha]_D +33.4^\circ$  (benzene).

**Acetolysis of Optically Active 3-*exo*-Methyl-2-*endo*-norbornyl *p*-Bromobenzenesulfonate (4, X = OBs).** From the product mixture formed by sodium acetate buffered acetolysis of 4, X = OBs, prepared from (+)-4, X = OH,  $[\alpha]_D +19.9^\circ$  (carbon tetrachloride), 62.4% optically pure, one can isolate by vapor chromatography (+)-3-*endo*-methyl-2-*exo*-norbornyl acetate (9),  $[\alpha]_D +5.29^\circ$  (absolute ethanol), and (+)-7-*anti*-methyl-2-*exo*-norbornyl acetate (8),  $[\alpha]_D +9.18^\circ$  (95% ethanol). Since 9 of  $[\alpha]_D -1.85^\circ$  has the same optical purity as 7 of  $[\alpha]_D +16.5^\circ$ ,<sup>15</sup> whereas the starting alcohol 4, X = OH, corresponds to 7 of  $[\alpha]_D (19.9/14.4) \times 33.4 = 46.1^\circ$ , the rotation calculated for 9 isolated from the solvolysis with complete retention of optical purity is  $(46.1/16.5) \times 1.85^\circ = 5.18^\circ$ . The observed value of  $5.29^\circ$  thus corresponds to 102% retention. Similarly, 8 has<sup>15b</sup> 1.72 times the rotation of 9 of equal optical purity in the indicated solvents. The calculated value of  $1.72 \times 5.18^\circ = 8.91^\circ$  is matched by the observed value  $9.18^\circ$ , corresponding to 103% retention. The configurations are as shown<sup>15a,b</sup> and are those expected for a Wagner-Meerwein related pair of products derived from cation A<sub>2</sub> which is in turn formed by 6,2-hydride shift in cation C<sub>1</sub> (Scheme II). The complete preservation of optical purity in these products generated from entry *via* cation C<sub>1</sub> in the present work and *via* cation A<sub>2</sub> in the previous work<sup>15c</sup> shows that vicinal (3,2) secondary-secondary shift of hydrogen or methyl, whether *endo* or *exo*, is very slow relative to 6,2 shift and solvent capture. This is a desirable feature of the experimental system. It eliminates one conceivable source of racemization which, if it had occurred, could have complicated the issue, since it would have been superimposed upon any racemization caused by competition between Schemes I and II.

The optical purity of 8 and 9 (X = OAc) also excludes the possibility of another formally conceivable (although *a priori* unlikely) racemizing mechanism involving 5,2-hydride shift. In cation C<sub>1</sub>, this would produce either the 6-methyl-2-norbornyl cation (products from which are not observed<sup>15a,b</sup>) or the enantiomer of A<sub>2</sub>. Hence if 5,2 shift were slower than 6,2 shift, the competition would cause some racemization in products 8 and 9; if the relative rates were in the opposite order, the configurations of 8 and 9 would be enantiomeric with those observed.

The tertiary product 2-*endo*-methyl-2-*exo*-norbornyl acetate is very difficult to isolate from the product mixture. It is present in small amounts and emerges in the early fraction from vapor chromatographic

columns with a retention time very close to those of 1-methyl-2-*exo*-norbornyl acetate and 2-*exo*-methyl-2-*endo*-norbornyl acetate, which also are present. The rotation of this three-component mixture, which is readily separable from all the other products by vpc, shows that the 2-*endo*-methyl-2-*exo*-norbornyl acetate in it is (+) (see Experimental Section) and hence that it has configuration 5b, consistent with its formation at least predominantly by Scheme II. Unfortunately, acetate 5b is not completely stable on the vpc columns (tricyanoethoxypropane stationary phase) most efficient for its separation from the remaining two contaminants unless extreme care is taken to deacidify the column and injector surfaces by injection of ammonia between passes. With considerable labor, (+)-2-*endo*-methyl-2-*exo*-norbornyl acetate (5b) can be obtained free of the other two persistently adhering isomers but now contaminated with decomposition products from the column stationary phase. The rotation of this material is  $[\alpha]_{365} +6.18^\circ$  (chloroform), which confirms the configuration as 5b and represents 75% retention of optical purity.<sup>15a,b</sup> This is a minimum value because of the presence of inert diluents, but still demonstrates that the more circuitous mechanism of Scheme II, involving only *exo*-3,2-hydride shift, accounts for at least 87.5% of the tertiary product acetate.

That this estimate is actually much too conservative is indicated by a comparison of the product ratios from the acetolysis of 3-*exo*-methyl-2-*endo*-norbornyl substrate (4, X = OBs) with those from the 3-*endo*-methyl-2-*exo*-norbornyl series 9 (X = OBs).<sup>15</sup> In the latter

case, the ratios of tertiary product 2-*endo*-methyl-2-*exo*-norbornyl acetate (5b) to secondary products 9 (X = OAc) and 8 are 0.242 and 0.229.<sup>16</sup> These ratios represent the partition of cation A<sub>2</sub> between solvent capture and *exo* tertiary-secondary 3,2-hydride shift to give cation C<sub>2</sub>. Scheme II postulates that all of the tertiary product 5b from 3-*exo*-methyl substrate 4 (X = OBs) arises from C<sub>2</sub> which is derived solely from the same cation, A<sub>2</sub>. If this is correct, the corresponding product ratios from 4 (X = OBs) should be identical with those from 9 (X = OBs). Any tertiary product 5a formed by direct *endo*-3,2-hydride shift in the alternative mechanism (Scheme I) would make the product ratios 5:9 and 5:8 from 4 (X = OBs) higher than those from 9 (X = OBs). In fact, since tertiary cation C<sub>2</sub> (or its enantiomer A<sub>1</sub>) gives essentially all tertiary product under the acetolysis conditions,<sup>16</sup> the excess of tertiary product from 4 (X = OBs) over that predicted by the 5b:9 and 5b:8 product ratios from 9 (X = OBs)

(16) Paper IV: J. A. Berson, A. W. McRowe, and R. G. Bergman, *J. Am. Chem. Soc.*, **89**, 2573 (1967).

is a direct measure of the incursion of any extra path, such as the *endo*-shift mechanism of Scheme I, by which tertiary product might be formed.

Experimentally, these ratios can be determined to about  $\pm 1\%$  accuracy by direct capillary vapor chromatographic comparisons of peak areas.<sup>16</sup> The determination is much more accurate than that involved in estimation of the yield of a minor constituent of a multi-component mixture, where summations of experimental errors become important. In the calculation of "tertiary product" from 4 (X = OBs), the 1-methyl-2-*exo* (3b) and 2-*exo*-methyl-2-*endo* (10) acetate products are combined with 5b since control experiments show that they are artefacts derived from it by prolonged exposure to the solvolysis conditions.<sup>16</sup> In the case of the much

more reactive substrate 9 (X = OBs), 3b and 10 are not found since complete solvolysis is achieved in a shorter time.<sup>15</sup>

The ratios of "tertiary product" to 9 and 8 from 4 (X = OBs) are 0.247 and 0.233, which are in both cases identical within experimental error with those found from 9 (X = OBs).<sup>16</sup> Thus, a maximum of 2% of the "tertiary product" can have been formed by the *endo*-shift path of Scheme I.

A more revealing estimate of the stringency of the interdiction against *endo*-3,2 shift is given by comparison of the relative importance of *exo*-3,2 shift in A<sub>2</sub> (Scheme II) with the relative importance of *endo*-3,2 shift in C<sub>1</sub> (Scheme I). Cation A<sub>2</sub> gives rise to 7% yield of tertiary product 5b, of which 100% comes from *exo*-3,2-hydride shift.<sup>15</sup> Cation C<sub>1</sub> gives rise to 3.4% yield of "tertiary product" (5b + 3b + 10<sup>16</sup>) of which at most 2% comes from *endo*-3,2-hydride shift. Thus, relative to the competing processes 6,2-hydride shift and solvent capture, *exo*-3,2-hydride shift in A<sub>2</sub> is at least 100 times as efficient as is *endo*-3,2 shift in C<sub>1</sub>.

**Demonstration that *exo*-Vicinal Hydride Shift is Much Faster than *endo* ( $k_7 \gg k_5$ ).** In interpreting the high selectivity implied by these observations on two separate molecules, one must establish that they are attributable to an intrinsically greater rate of *exo*-hydride migration in cation A<sub>2</sub> than of *endo*-hydride migration in cation C<sub>1</sub> and not to some extraneous cause irrelevant to the test at issue. The misleading effects of failure to do this can be illustrated with the help of Scheme III, which shows the "core" cycle<sup>12</sup> of cations C<sub>1</sub>, A<sub>2</sub>, and B<sub>3</sub> interconnected by 6,2-hydride shifts. Entry or exit is effected *via* any of the cations from the structurally related substances: C<sub>1</sub> is connected with 4 (X = OBs) and with 1 and 11 (X = OAc), A<sub>2</sub> with 9 (X = OBs) and with 9 and 8 (X = OAc), and B<sub>3</sub> with 12 and 13 (X = OBs or OAc).<sup>16</sup> Schemes I and II,

which involve cations C<sub>1</sub> and A<sub>2</sub>, respectively, are excerpts from Scheme III. Escape from the "core" cycle

Scheme III

to the "periphery" (A<sub>2</sub> → C<sub>2</sub>) has been shown to be essentially irreversible.<sup>16</sup>

The experiments of the present and preceding<sup>15</sup> paper demonstrate that the ratio of product 5b derived from the sequence of cations A<sub>2</sub> → C<sub>2</sub> by *exo*-hydride shift to product 5a from the sequence C<sub>1</sub> → A<sub>1</sub> by *endo*-hydride shift is always high, regardless of the point of entry into the scheme. Although this result is consistent with the interpretation that the rate of *exo* shift is intrinsically much greater than that of *endo* shift ( $k_7 \gg k_5$ ), in itself it does not require it. An alternative explanation would permit  $k_7 \cong k_5$  but would attribute the predominance of *exo*-hydride shift to an entirely unrelated cause, namely a large discrepancy in stability between the "core" cations C<sub>1</sub> and A<sub>2</sub>. If A<sub>2</sub> were in fact much more stable than C<sub>1</sub> ( $k_1 \gg k_2$ ), the "core" cycle would have a built-in mechanistic gradient, so that points entering the energy surface at A<sub>2</sub> would have difficulty climbing to C<sub>1</sub> at a rate competitive with exit to product, and points entering at C<sub>1</sub> might slide down to A<sub>2</sub> fast enough to preclude appreciable competition from *endo* shift. Furthermore, it would not be difficult to construct a physically reasonable case for the idea that cation A<sub>2</sub> is more stable than cation C<sub>1</sub>. For example, one might argue that the two sites of positive charge in the latter are shielded by the methyl group and hence perhaps the solvation energy is less. In fact, a similar argument has been invoked<sup>17</sup> to account for certain behavior of 2-aryl-3-hydroxynorbornyl cations. We shall return to a discussion of these

(17) D. C. Kleinfelter and T. E. Dye, *J. Am. Chem. Soc.*, **88**, 3174 (1966).

cases but point out here that in principle the argument does not depend upon the assumption<sup>17</sup> that 6,2-hydride shift is very fast relative to 3,2 shift (which clearly is not the case in our system<sup>18</sup>) but merely requires  $k_1 \gg k_2$ .

It can be shown that the requirements of the alternative explanation ( $k_1 \gg k_2$  and  $k_7 \cong k_8$ ) cannot be fitted to the rest of the product distribution in the present case and hence that the alternative is excluded. In particular, it is intuitively obvious by inspection that if  $A_2$  and  $B_2$  do not differ appreciably in energy (as seems reasonable),  $k_1 \gg k_2$  requires that entry at  $A_2$  preclude the formation of any appreciable amounts of products 3-*exo*-methyl-2-norbornyl acetate (11, X = OAc) and 7-*syn*-methyl-2-*exo*-norbornyl acetate (1, X = OAc), derived from  $C_1$ . This can be shown analytically by a steady-state treatment of the cations of Scheme III, from which the product ratio 5b:5a from 3-*exo*-methyl-2-*endo*-norbornyl starting material (4, X = OBs) is given by eq 1.

(5b:5a)<sub>4</sub> =

$$\frac{k_7 \left[ \frac{k_1(2k_6 + k_2 + k_3)}{k_5[(k_2 + k_3)(2k_6 + k_2 + k_3) + k_7(k_6 + k_2 + k_3)]} \right]}{k_8} \quad (1)$$

Since this ratio is experimentally at least 50, it follows from eq 1 that if the vicinal shift ratio  $k_7:k_8$  is about unity,  $k_1$  must be at least  $50k_8$ .

Equation 2 expresses the ratio of products 1 and 11 (derived from cation  $C_1$ ) relative to 12, 13, 9, and 8 (derived from cations  $B_2$  and  $A_2$ ) when the core cycle is entered at  $A_2$  via 9 (X = OBs) starting material. Since

$$[(1 + 11)/(8 + 9 + 12 + 13)]_0 =$$

$$k_2 k_4 / [2k_1 k_2 + k_3(k_4 + k_5)] \quad (2)$$

the rate constants for capture of the hindered cation  $C_1$  at the two Wagner-Meerwein-related sites are in the ratio of about 5:1,<sup>16</sup> it seems quite reasonable to suppose that a factor about half this large favors attack on unhindered cation  $A_2$  relative to that on  $C_1$ , i.e.,  $k_3/k_4 \sim 2.5$ . Experimental support for this assumption is given by the detailed product distributions,<sup>16</sup> which show that capture of  $C_1$  must be considerably slower than capture of  $A_2$ . With  $k_1/k_2 \geq 50$ , the maximum permissible value for the product ratio of eq 2 is thus 0.004. That is, *syn*-7-methyl-2-*exo* (1) and 3-*exo*-methyl-2-*exo* (11) products could not be formed from 3-*endo*-methyl-2-*exo* starting material (9, X = OBs) in any amount greater than 0.4% of the total of products 12, 13, 8, and 9 (X = OAc). But the experimentally determined<sup>16</sup> product distribution is 9.2%. Thus, entry into the "core" cycle at cation  $A_2$  produces much more product from cation  $C_1$  than would be permitted if the equilibrium constant favoring  $A_2$  over  $C_1$  ( $k_1/k_2$ ) were large enough to ensure the observed exclusive *exo*-hydride shift. Of course, as eq 1 shows,  $k_1 > k_2$  reinforces  $k_7 > k_8$ ; that is, the thermodynamic bias in question would increase the selectivity. However, even taking this into account, one cannot avoid having  $k_7 \gg k_8$ . Thus, with  $k_3/k_4 \sim 2.5$ , in order for the term  $k_7 k_1 / k_8 k_2$  to be greater than 50 (see eq 1) the experimental product ratio can be fitted in eq 2 only by values of  $k_7/k_8 \geq 23$ . The heavy predominance of 3,2-*exo*- over 3,2-*endo*-hydride shifted product therefore signifies a large difference in the rates of the two processes themselves.

**Elimination of a Hypothetical Alternative.** In a purely formal sense, the stereochemical outcome of Scheme II ( $4 \rightarrow C_2 \rightarrow 5b$ ) can be duplicated by a hypothetical alternative mechanism (Scheme IV). This in-

Scheme IV

volves 3,2-hydride shift in cation  $B_2$  to produce the 6-methyl cation  $B_4$ , followed by *exo-exo* hydride shift to give  $C_2$  rather than *endo-endo* shift to give  $A_1$ . This path is readily ruled out on the grounds that, first, the required exclusive *exo-exo* 6,2 shift ( $B_4 \rightarrow C_2$ ) is highly implausible, since closely related cases of 6,2 shift are exclusively *endo-endo*,<sup>18</sup> and, second, the required 3,2 secondary-secondary shift  $B_2 \rightarrow B_4$  does not occur under the reaction conditions.<sup>16</sup>

**Comparison with Other Systems.** An investigation based upon the observed<sup>19</sup> rearrangement of 2-*endo*-phenyl-2,3-*cis,exo*-norbornanediol (14, R =  $C_6H_5$ ) to 3-*endo*-phenyl-2-norbornanone (15a or b, R =  $C_6H_5$ ) showed<sup>20a</sup> that the reaction in the optically active series did not give 15a, the product of direct 3,2-hydride shift, but instead proceeded by way of preliminary 6,2-hydride shift ( $16 \rightarrow 18$ ) followed by *exo-exo* 3,2-hydride shift to give 15b, enantiomeric with 15a. The formation of 15b thus uses a mechanism similar to that by which 3-*exo*-methyl-2-*endo*-norbornyl starting material (4, X = OBs) gives 2-*endo*-methyl-2-*exo*-norbornyl product 5b instead of its enantiomer 5a. The preference for *exo-exo* 3,2 shift is not quantitatively evaluable from this result since, in the system generated from 14, the products of the two competing kinds of 3,2-hydride shift are different substances (17 and 15b), and a measure of the relative importance of the two processes depends on the product composition, 15b:17, not the enantio-

neric composition, 15a:15b. The 15b:17 ratio previously<sup>20a</sup> was implied to be large and now is estimated<sup>20b</sup> as  $\geq 200$ .

It is difficult to evaluate the selectivity that obtains in the related case<sup>17</sup> of 2-endo-*p*-anisyl-2,3-*cis,exo*-norbornanediol (14, R = *p*-MeOC<sub>6</sub>H<sub>4</sub>), where the authors,<sup>17</sup> on the basis of the observation that "the only nonacidic compound isolable was 3-endo-*p*-anisylnorbornanone in ca. 50% yield," concluded that a large preference for *exo*-3,2 shift existed in their system. Such a preference may well exist but is not demonstrated by the facts disclosed. Similarly, the isolation<sup>8</sup> of olefin 18 from *p*-anisylcamphenilol (19) does not of itself indicate a large preference for *exo*-3,2-methyl migration, and in fact was not so interpreted.<sup>8</sup> Brown,<sup>21</sup> in discussing the effect of substitution at the migration terminus on the stereoselectivity of 3,2 shift in norbornyl cation, has referred to the above examples (14,

R = C<sub>6</sub>H<sub>4</sub>, and 19) as demonstrating highly selective *exo*-3,2 shift and has stated that "the insensitivity of the stereoselectivity to the stability of the cationic center, even with a group as stabilizing as *p*-anisyl, suggests that the steric interpretation is to be preferred" (to the

(21) H. C. Brown, *Chem. Brit.*, 2, 199 (1966).

nonclassical interpretation). Regardless of what such invariance might mean if it were eventually established (as may well turn out to be the case), it is clear that in the light of the above discussion, an experimental basis for the argument is not yet available.

One must also keep in mind the more general admonition that any evaluation of "invariance" or "insensitivity" is on weak grounds if based upon a set of experimental data all of which show "complete" preference for one path over another. Wide variations in actual sensitivity may hide beneath an apparent "insensitivity" which is attributable to nothing more than a choice of systems that all have selectivities so high that they lie at the extreme edge of the available experimental techniques and thus cannot be ranked. Of course, even worse confusion results if one insists that actually observed variations are to be ignored. Thus, the observation<sup>22</sup> that sodium borohydride attacks the 2-*p*-anisylbornyl cation with an *exo:endo* preference of 6.5 has been taken<sup>22</sup> to represent "no major change" in selectivity as compared to the attack of acetic acid on norbornyl cation, which shows<sup>23</sup> an *exo:endo* preference of 9140.

A large preference for *exo*-3,2-methyl migration is demonstrated in the 2,3,3-trimethylnorbornyl,<sup>24a,b</sup> 2,3,3-trimethyl-1-hydroxynorbornyl,<sup>24c</sup> and 2,3-dimethyl-3- $\beta$ -carboxyethylnorbornyl<sup>24d</sup> cations since in those cases, like the 3-methylnorbornyl case reported here, *enantiomeric composition* is directly translated into product composition, and analysis for structurally isomeric substances is unnecessary. The trimethylnorbornyl cases,<sup>24a-c</sup> which involve *intramolecular* competition between migrating groups, are also free of any ambiguity arising from built-in mechanistic bias caused by a large difference in stability between two different cationic intermediates.

We can now provide an additional example of the two-product type in the case of 3-endo-methyl-*cis,exo*-2,3-norbornanediol (14, R = Me), which rearranges

Scheme V

(24) (a) P. Hirsjärvi, K. Heinonen, and L. Pirilä, *Suomen Kemistilehti*, B37, 77 (1964); (b) W. R. Vaughan, C. T. Goetschel, M. H. Goodrow, and C. I. Warren, *J. Am. Chem. Soc.*, 85, 2282 (1963); (c) A. M. T. Finch, Jr., and W. R. Vaughan, *ibid.*, 87, 5520 (1965); (d) G. E. Gream and D. Wege, *Tetrahedron*, 22, 2583 (1966).

in aqueous sulfuric acid to give exclusively 3-*endo*-methyl-2-norbornanone (15b, R = Me). This substance is readily separable by capillary vpc from its *exo* epimer (17), the presence of which to the extent of 0.03% would have been detectable. Although we have no direct evidence that the rearrangement is intramolecular and involves the route  $14 \rightarrow 16 \rightarrow 18 \rightarrow 15b$  demonstrated<sup>20</sup> for the phenyl case, adoption of such an assumption means that the *exo-exo* shift path is preferred to the *endo-endo* by a factor of at least 3300.

The acid-catalyzed rearrangement of the sesquiterpene hydrocarbon longifolene (20) to isolongifolene (21)<sup>25</sup> has been formulated<sup>26</sup> as in Scheme V with an *endo*-3,2-methyl shift (heavy arrow). In the present context, however, it would be plausible to postulate as an at least equally probable alternative the mechanism shown in Scheme VI, which employs a more cir-

Scheme VI

cuitous sequence involving instead an *exo*-3,2-methyl shift (heavy arrow). The two mechanisms are not distinguishable by ordinary methods of configurational correlation since both produce the same enantiomer of the rearranged product 21 from a given enantiomer of the starting material 20. They differ most directly in the relationship of the two carbon atoms indicated with heavy dots. These remain contiguous in Scheme VI but assume a 1,3 relationship in the product of Scheme V.

**Contrasting Stereochemistry of 6,2- and 3,2-Hydride Shifts.** The transition state or intermediate for the exclusively *endo-endo* 6,2- (or 6,1-) hydride shift observed in the known examples<sup>18</sup> is readily achieved by a very minor adjustment of atomic positions in the norbornyl nonclassical ion 22. Thus, a slight movement of a C-6 hydrogen in the indicated direction produces the theoretically favorable<sup>27</sup> edge-protonated cyclopropane species and results in *endo-endo* shift stereochemistry.

Brown<sup>22</sup> comments that it is "remarkable" that 6,2 shift is fast enough to compete with solvent capture, since "normally it is considered that the nonclassical structure protects the ion from such attack in the *endo* direction." However, since the ground states of the *intramolecular* 6,2 shift and the *intermolecular* solvent capture are entirely different, a comparison of the rates of the two processes is difficultly interpretable.

**Significance of the Preference for *exo*-3,2 Shift.** The present demonstration that *exo*-3,2 shift is highly preferred to *endo* is completely in accord with the behavior expected of a nonclassical ion. Although opening of the mesomeric bridge with inversion by an external or internal nucleophile usually has been rationalized by stereochemical analogy to simpler nucleophilic displacements (S<sub>N</sub>2), there are also strong quantum mechanical reasons for expecting this behavior. The argument can be given as an adaptation of one already put forward in another connection.<sup>28</sup> The transition state for the substitution reaction in its most primitive form is a three-center problem which can be treated by simple LCAO methods. Regardless of what orbitals are chosen for the basis set, the idealized case will be one with equal bond integrals ( $\beta$ ) between the central atom and its two attached groups. For the linear (or approximately linear), inversion-producing relationship of these centers, A-B-C, one can assume a zero A-C integral, which leads to one bonding, one nonbonding, and one antibonding level, as has previously been noted.<sup>29</sup> For the retention-producing orientation, with an acute A-B-C angle, the A-C integral becomes finite ( $k\beta$ ) and the system becomes cyclic. This has the consequences that the energy of the bonding level of the primitive linear case is lowered but that of the nonbonding level is raised (to antibonding) by a greater amount. Therefore, the four-electron (nucleophilic) system will prefer the linear geometry, but the two-electron (electrophilic) system will prefer the bent.<sup>30</sup> The assumptions of simple LCAO theory are so severe that one should not be surprised if other factors exert a large enough influence to cause occasional contraventions of the predicted behavior. Nevertheless, the underlying quantum mechanical effects are inescapably present.

An extension of the argument to nucleophilic attack on a nonclassical carbonium ion intermediate would treat the system as a four-electron, four-center case 23, with nonclassical bonding in the three-membered cycle

(30) Crudely, the linear system is related to allyl whereas the bent is related to cyclopropenyl.

BDC, and partial bonds A-B and B-C representing the onset of attachment of the nucleophile (A) to one terminus (B) and detachment of the bridging atom (C) from B. The inversion mode would correspond to the linear  $SN_2$  case, with no A-C interaction ( $k = 0$ ), but the retention mode would have  $k > 0$ . Simple LCAO calculations on this four-center problem give results qualitatively similar to those for the three-center case. (The system 23 with  $c = 0$  is essentially the same used<sup>28</sup> to discuss the stereochemistry of additions to olefins or eliminations forming them). Over reasonable variations of the parameters  $a$ ,  $b$ ,  $c$ , and  $d$  of 23, the four-electron (nucleophilic) system is always destabilized by inclusion of a front-side interaction ( $k > 0$ ).

Similarly, 3,2 shift in a norbornyl cation may be treated as a five-center, four-electron case 24. Migration of R on the *endo* side of the cation will correspond to front-side opening of the C-6-C-1-C-2 mesomeric

23

24

bridge and will introduce a C-6-R interaction which will be absent in *exo* migration. Again, simple LCAO calculations show this interaction to have a net destabilizing effect in the four-electron case. On this basis, *exo* migration should be favored, as is found experimentally.<sup>31</sup>

The preference for *exo*-3,2 shift is inexplicable in terms of the windshield-wiper effect, which has been postulated<sup>32</sup> to account for *exo* capture of norbornyl cations by external nucleophiles.<sup>33</sup> This effect is supposed to operate by the rapid back-and-forth motion of C-6 between C-1 and C-2, which produces an abnormally low nucleophile concentration in the *endo* direction.<sup>32</sup> In the case of 3,2 shift, however, the nucleophile, migrating hydride, is intramolecular and its "concentration" cannot be affected by the rapid motion. The present observations therefore require some other explanation.

One could argue<sup>21</sup> that the results are caused by purely steric factors in the classical ion rather than stereoelectronic factors in the nonclassical one. Some such postulate is needed whether the classical ions are the dominant intermediates in solution<sup>21</sup> or only present in small concentration.<sup>31b</sup> However, it is not obvious that *exo* stereochemistry then should be heavily favored. Although the transition state for *endo* migration is thought to place the migrating hydrogen close to the 5,6-ethylene bridge,<sup>21</sup> the transition state for *exo* migra-

(31) (a) Arguments<sup>31b</sup> favoring the nonclassical structure for norbornyl cation based on the slower rate of 3,2 shift compared to vicinal shift in open-chain systems are debatable, since the alignment of either of the C-H bonds at C-3 in a hypothetical classical norbornyl cation may be much less favorable than that accessible in a more or less freely rotating open-chain case. tion would force the migrating hydrogen to brush past the *syn*-7-hydrogen. These effects presumably would be offset to some unknown extent by diminution of certain ground-state repulsive forces. The interactions relieved would include a 3,5 interaction in the *endo* case (similar to a 1,3-diaxial interaction in boat cyclohexanes) and a 3,4 interaction in the *exo* (similar to a 1,2-diequatorial interaction). At present, a reliable way to estimate the balance of these factors is lacking. It seems to us preferable, therefore, to employ the nonclassical formulation, which predicts the observations.<sup>33g</sup>

## Experimental Section

**Optical Activation of 3-*exo*-Methyl-5-norbornene-2-*endo*-carboxylic Acid.** Combination of quinidine alkaloid in absolute ethanol with 1.15 molar equiv of the acid and storage of the resulting solution gave a precipitate of the mixed salts. If smaller proportions of acid were used, the free alkaloid tended to crystallize out. Three recrystallizations gave material from which 40% of the original weight of acid could be obtained with  $[\alpha]_D^{25} -129^\circ$  (95% ethanol). Seven further recrystallizations from methanol gave material of  $[\alpha]_D^{25} -151^\circ$ . Dextrorotatory acid was obtained from the mother liquors. The resolution was not pressed further.

(-)-Methyl 3-*exo*-Methyl-5-norbornene-2-*endo*-carboxylate. The ester was obtained by treatment of a distilled sample of the corresponding acid with ethereal diazomethane. Distillation gave ester that was homogeneous on column L and had an infrared spectrum identical with that of the racemate. Acid of  $[\alpha]_D^{25} -130.4^\circ$ ,  $[\alpha]_{25}^{25} -434.1^\circ$ , gave ester of  $[\alpha]_D^{25} -134.2^\circ$ ,  $[\alpha]_{25}^{25} -446.2^\circ$  ( $c$  5.7, 95% ethanol).

**Correlation with 3-*exo*-Methyl-2-*endo*-norbornanecarboxylic Acid.** The above unsaturated acid,  $[\alpha]_D^{25} -130.4^\circ$ , was dissolved in methanol and hydrogenated at 40-20 psi with platinum oxide catalyst. Shaking in the Parr apparatus for 5 min was sufficient to complete the reaction. The saturated acid was distilled bulb to bulb at reduced pressure to produce a crystalline mass. The infrared spectrum in carbon disulfide was identical with that of the pure racemic compound. The rotation was obtained from an aliquot taken from a molten, homogeneous product,  $[\alpha]_D^{25} -40.5^\circ$ ;  $[\alpha]_{25}^{25} -110^\circ$  ( $c$  10.8, 95% ethanol).

A homogeneous sample of the above acid,  $[\alpha]_D^{25} -40.5^\circ$ , was quantitatively converted to its methyl ester with ethereal diazomethane. The distilled product, pure on columns L and N, had an infrared spectrum identical with that of the pure racemic compound and  $[\alpha]_D^{25} -38.2^\circ$ ;  $[\alpha]_{25}^{25} -103^\circ$  ( $c$  5.9, 95% ethanol).

**Optically Active 3-*exo*-Methyl-2-*endo*-acetylnorbornane (4, X = COCH<sub>3</sub>).** Pure 3-*exo*-methyl-2-*endo*-norbornanecarboxylic acid,  $[\alpha]_D^{25} +31.4^\circ$  ( $c$  4.6, 95% ethanol), was converted to the acid chloride with thionyl chloride and distilled in 93.4% yield. The acid chloride was immediately converted to the methyl ketone *via* the methylcadmium reagent in ether and distilled to give a 91% yield. The product had infrared spectrum and retention times on vpc (columns L and N) identical with those of the racemic com-

(33g) NOTE ADDED IN PROOF. Although both steric and torsional effects have been proposed as alternative explanations for *exo* attack of nucleophiles [by H. C. Brown, *Chem. Eng. News*, 45, 87 (1967), and by P. von R. Schleyer, *J. Am. Chem. Soc.*, 89, 701 (1967), respectively], it is questionable whether quantitative estimates of the magnitudes of these effects can be given. For example, both Brown and Schleyer have used them to explain the reported demonstration [A. F. Thomas and B. Willhalm, *Tetrahedron Letters*, 1309 (1965); A. F. Thomas, R. A. Schneider, and J. Meinwald, *J. Am. Chem. Soc.*, 89, 68 (1967)], by an nmr method, that camphor exchange its 3-*exo*-hydrogen for deuterium much more rapidly than its 3-*endo*-hydrogen. Brown and Schleyer have argued that the preferred *exo* stereochemistry of carbonium ion capture, by analogy, does not demand a nonclassical explanation. However, additional observations on the exchange require quite a different interpretation. Thomas, *et al.*, report, without further comment, mass spectrometric data which show that camphor-3,3-*d*<sub>2</sub>, 97% deuterated, exchanges with water to give a mixture of 21% *d*<sub>2</sub>, 64% *d*<sub>1</sub>, and 15% *d*<sub>0</sub> camphor. This composition is incompatible with a large difference in exchange rate for the 3-*exo*- and 3-*endo*-deuteriums. Since steric and torsional effects previously were postulated to be consistent in direction and magnitude with the reported highly stereospecific *exo* exchange, the observed low stereospecificity now necessitates a revision of the basis for quantitative estimation of the proposed effects.

pound, which had been prepared in the same way.<sup>34</sup> Less than 0.5% impurity was detected,  $[\alpha]^{25}_D -10.8^\circ$ ;  $[\alpha]^{25}_{488} -224^\circ$  (c 4.6 chloroform).

**Optically Active 3-*exo*-Methyl-2-*endo*-norbornyl Acetate.** Methyl ketone 4, X = COCH<sub>3</sub>,  $[\alpha]_D -7.59^\circ$  (c 4.8, chloroform), was treated with a chloroform solution of peroxybenzoic acid with a catalytic amount of boron trifluoride etherate added. After 1 week, the mixture, consisting of 70% acetate 4, X = OAc, and 30% starting ketone, was worked up and resubjected to the same reagents for another 10 days to give 97% of the desired acetate and 3% unreacted ketone. The acetate was purified by preparative vpc on column C to yield homogeneous product (columns L and N) in a 58% over-all yield from ketone. Retention times on vpc and the infrared spectrum of this material were identical with those of the pure racemic material;  $[\alpha]^{25}_D +19.1^\circ$  (c 6.8, carbon tetrachloride);  $[\alpha]^{25}_{488} +25.6^\circ$  (c 5.4, chloroform).

**Optically Active 3-*exo*-Methyl-2-*endo*-norbornanol (4, X = OH).** Chemically pure acetate 4, X = OAc,  $[\alpha]_D +35.5^\circ$  (chloroform), was reduced in high yield with lithium aluminum hydride to the alcohol whose infrared spectrum in carbon tetrachloride was identical with that of the racemic material.<sup>34</sup> The material, which was pure by vpc (columns L and N), was solid at 0°, but became partially liquid at room temperature; rotations from a molten, homogeneous sample:  $[\alpha]^{25}_D +19.87 \pm 0.09^\circ$  (c 4.5–5.3, carbon tetrachloride).

**Correlation of 3-*exo*-Methyl-2-*endo*-norbornanol with Camphenilone (+)–7.** A solution of 85 ml of acetone, reagent grade, and 3.51 g (27.8 mmoles) of alcohol 4, X = OH,  $[\alpha]^{25}_D +14.4^\circ$  (c 5.0, carbon tetrachloride), was oxidized with a slight excess of Jones reagent. The reaction mixture was diluted with 350 ml of saturated brine and extracted six times with a total of 500 ml of pentane. The combined organic layers were washed twice with saturated brine and dried successively over sodium sulfate and calcium sulfate. The solvent was carefully distilled off through a short Vigreux column and the residue was distilled at 60–61° (10 mm). The yield was 2.38 g (69%) of product consisting of 96% 3-*exo*-methyl-2-norbornanone and 4% the *endo*-methyl isomer.

The above ketone mixture (ca. 19 mmoles) was directly taken up in 45 ml of dry tetrahydrofuran and heated with vigorous stirring for 12 hr with approximately 1.0 g of sodium hydride (pearls, not a fine dispersion). The addition of 13 ml (ca. 0.2 mole) of distilled methyl iodide was effected over 2 hr, and the stirring and refluxing were continued another 3 hr. On cooling, 50 ml of water was added, and the two resulting layers were extracted six times with a total of 200 ml of pentane. The combined organic layers were dried successively over sodium sulfate and calcium sulfate. The solvent was carefully distilled off, and the residue was distilled at 60° (10 mm) to yield 2.3 g (90%) of a waxy solid. Analysis on capillary column L indicated approximately 5% high-boiling hydrocarbon impurity; the remainder was camphenilone. Purification was achieved by preparative vpc on column C. The pure product (columns L and N) had an infrared spectrum and retention times on capillary vpc identical with those of pure commercial camphenilone (Light, Ltd., London);  $[\alpha]^{25}_D +33.4^\circ$  (c 7.7, benzene).

**Optically Active 3-*exo*-Methyl-2-*endo*-norbornyl *p*-Bromobenzenesulfonate (4, X = OBr).** To a sample of 18.0 g (0.1428 mole) of alcohol 4, X = OH,  $[\alpha]_D +19.87^\circ$  (carbon tetrachloride), dissolved in 100 ml of pure, dried pyridine, was added 36.5 g (0.1428 mole) of *p*-bromobenzenesulfonyl chloride, freshly recrystallized. The solution was allowed to stand at +5° for 4 days and then worked up with 1.5 l. of ether and 150 ml of water and ice. The ethereal solution was washed once with ice-cold 5% hydrochloric acid and thrice with saturated brine. The solution was dried twice over sodium sulfate and concentrated on a rotary evaporator to give a colorless residue containing pyridine. The residue was held under vacuum (0.2 mm) for 54 hr at room temperature. Besides pyridine, approximately 0.6 g of alcohol was recovered from the cold traps. The white, crystalline sulfonate had an infrared spectrum in carbon disulfide identical with that of the authentic material from the racemic series. No hydroxyl absorptions were present. The yield was 46.28 g (94%).

**Preparative Solvolysis of Optically Active 3-*exo*-Methyl-2-*endo*-norbornyl *p*-Bromobenzenesulfonate.** The above optically active *p*-bromobenzenesulfonate prepared from alcohol,  $[\alpha]_D +19.87^\circ$  (carbon tetrachloride), was washed into a 1-l. flask with dry acetic acid (650 ml) and 26.0 g (0.317 mole) of anhydrous sodium acetate.

Under a reflux condenser and drying tube, the flask was plunged into an oil bath at 100°; the temperature of the stirred solution had risen to 98° within 1 hr. The temperature was maintained at 98–100° for an additional 9.5 hr.

At the end of this time, the reaction mixture was poured into 2.5 l. of water and ice and extracted six times with a total of 2 l. of pentane. The combined organic layers were washed with successive 150-ml portions of water, saturated sodium bicarbonate solution, and twice with saturated brine. The light yellow solution was successively dried over two portions of sodium sulfate and one of calcium sulfate with a little Norit. The clear solution was filtered and carefully fractionated through a Vigreux column. An intense infrared spectrum of a neat sample of the clear yellow residue contained none of absorptions of the arenesulfonate or hydroxyl compounds. The yield of crude product, which contained less than 2% each of solvent and unidentified olefins (column N), was 22.3 g (99%).

The crude acetate mixture was dissolved in 70 ml of ether and reduced with 3.2 g (0.084 mole) of lithium aluminum hydride in 100 ml of ether in a 1-l., three-necked flask equipped with a Dry Ice condenser. The excess reagent and alkoxide salts were decomposed with a freshly prepared saturated solution of anhydrous sodium sulfate. The clear solution was decanted from the granular precipitate and the latter washed with 1 l. of ether. The ethereal solution was dried over sodium sulfate and carefully concentrated to yield a clear colorless residue. The white granular salts were dissolved in ice-cold hydrochloric acid, but yielded no extractable material.

Enough ether and absolute ethanol were added to completely dissolve the total, combined alcohol mixture obtained from concentration of the ether solution. Analysis on capillary column N indicated at least eight alcohols were present, of which the "tertiary alcohol mixture," consisting of 1-methyl-2-*exo*-norbornanol (3b), 2-*exo*-methyl-2-*endo*-norbornanol (10), and 2-*endo*-methyl-2-*exo*-norbornanol (5b), was present as a group eluting well ahead of the bulk of the alcohol mixture. This "tertiary alcohol mixture" consisted of 3.4% of the total alcohols.

The "tertiary alcohol mixture" was separated from the main bulk by preparative vpc (column A) under conditions separately shown in control experiments not to cause any interconversion or racemization of the alcohols of concern. The first eluted material was distilled bulb to bulb at room temperature (0.03 mm) to remove eluted column packing.

**Analysis of the "Tertiary Alcohol Mixture."** This alcohol mixture was shown to be contaminated with less than 0.3% of the alcohols of longer retention time which, as a group, were present in the same proportions as in the original solvolysis mixture. Of the two major alcohol peaks, 1-methyl-2-*exo*-norbornanol (3b) was  $13.0 \pm 0.7\%$  of the mixture as determined on capillary columns L and N. The standard deviation is given for four trials.

Two aliquots for the determination of the specific rotation of this mixture were carefully taken from the completely molten material to obviate any optical fractionation. The average specific rotations with the standard deviations were  $[\alpha]^{25}_D -4.51 \pm 0.005^\circ$ ;  $[\alpha]^{25}_{488} -13.93 \pm 0.016^\circ$  (c 5.5–6.6, chloroform).

The alcohol mixture was recovered from the rotation solutions, acetylated under the usual conditions, and distilled at 0.03 mm. The analysis of this mixture on capillary columns L and N gave the value for the 2-*endo*-methyl-2-*exo*-norbornyl acetate (15b) present as  $71.3 \pm 0.7\%$  over six determinations. A single determination of the specific rotations of the liquid acetate mixture gave  $[\alpha]^{25}_D -0.15^\circ$ ;  $[\alpha]^{25}_{488} -0.55^\circ$  (c 5.24, chloroform). With the observed rotation of  $-0.008$  and  $-0.029^\circ$ , respectively, the sodium D rotation is hardly useful except to confirm the sign; the accuracy of the mercury 365-mμ rotation is only about 10%.

The composition of the mixture may be calculated from the vpc data on both mixtures: 1-methyl-2-*exo*,  $13.0 \pm 0.7\%$ ; 2-*endo*-methyl-2-*exo*,  $71.3 \pm 0.7\%$ ; and 2-*exo*-methyl-2-*endo*,  $15.7 \pm 1.0\%$ .

**The Isolation of 2-*endo*-Methyl-2-*exo*-norbornyl Acetate (5b) from the "Tertiary Acetate Mixture."** Under normal conditions the tertiary *exo*-acetate 5b was found to decompose to elimination products when passed through preparative vpc columns. It was shown, however, that column A could be conditioned with many large injections of anhydrous ammonia gas to pass this acetate through in relatively good yield and to separate it from 1-methyl-2-*exo*-norbornyl acetate (3b) and 2-*exo*-methyl-2-*endo*-norbornyl acetate (10). In trials, optically active *t*-*exo* acetate 5b-OAc was obtained, after bulb-to-bulb distillation, with the same rotation as that injected. It was found necessary to condition the column with more ammonia after each injection of acetate 5b.

(34) Paper II: J. A. Berson, A. W. McRowe, R. G. Bergman, and D. Houston, *J. Am. Chem. Soc.*, **89**, 2563 (1967).

From the acetylated tertiary alcohol mixture obtained from the acetolysis of optically active 3-*exo*-methyl-2-*endo*-norbornyl *p*-bromobenzenesulfonate, 28.5 mg of the 2-*endo*-methyl-2-*exo*-norbornyl acetate (5b-OAc) was obtained after distillation at room temperature (0.03 mm). A small amount of white crystalline material was observed in the colorless liquid acetate. The entire distillate was washed into a volumetric flask for the rotation. From the observed rotation of  $+0.176^\circ$  at the mercury 365-m $\mu$  line, the specific rotation of  $[\alpha]^{25}_D +6.18^\circ$  (*c* 2.85, chloroform) was calculated. This would be equivalent to *t*-*exo* alcohol 5b-OH of  $[\alpha]_D -5.12^\circ$  (chloroform), or 46.5% optical purity.<sup>15a,b</sup> While this sample was pure by vpc on capillary column L, containing less than 0.5% of both *t*-*endo* acetate 10 and 1-methyl-2-*exo* acetate 3b, it undoubtedly was contaminated with a significant amount of some volatile material from the preparative vpc column resulting from continual treatment of the latter with ammonia. This contamination was evident both from the small amount of crystalline material observed in the sample and from the fact that the infrared spectrum of the chloroform solution used for the rotation showed diffuse absorption in the 2.5–3.0- $\mu$  range which was not present in the infrared spectrum of a chloroform solution of pure *t*-*exo* acetate 5b-OAc; the rest of the spectrum was identical with that of pure 5b-OAc.

**Isolation of 3-*endo*-Methyl-2-*exo*-norbornyl Acetate (9, X = OAc) and 7-*anti*-Methyl-2-*exo*-norbornyl Acetate (8).** These two substances emerged first and last, respectively, from the vapor phase chromatogram on column E of the secondary acetate fraction. This fraction was obtained by reacetylation of the alcohols remaining after separation of the "tertiary alcohol mixture" fraction from the solvolysis of optically active *p*-bromobenzenesulfonate. Two passes sufficed to give material that in each case was homogeneous (column L). The infrared and nmr spectra and retention times on capillary vpc (columns L and N) were identical with each sample's respective racemic counterpart.

The specific rotations of the 3-*endo*-methyl-2-*exo*-norbornyl acetate (9, X = OAc) were  $[\alpha]^{25}_D +5.29^\circ$ ;  $[\alpha]^{25}_{365} +8.52^\circ$  (*c* 5.2, absolute ethanol); and those of the 7-*anti*-methyl-2-*exo*-norbornyl acetate (8) were  $[\alpha]^{25}_D +9.18^\circ$ ;  $[\alpha]^{25}_{365} +31.47^\circ$  (*c* 5.6, 95% ethanol).

A sample of unfractionated secondary acetate mixture, free of solvent, had the specific rotation of  $[\alpha]^{25}_D -2.80^\circ$  (*c* 4.8, *l* = 4, chloroform).

**The Stability of the Acetolysis Products.** A stock solution of 5.88 g (30.9 mmoles) of *p*-toluenesulfonic acid monohydrate, 6.00 g (73.2 mmoles) of anhydrous sodium acetate, and 3.33 g (32.6 mmoles) of acetic anhydride in 150 ml of dried acetic acid was prepared to simulate closely the ionic concentrations at the end of the acetolysis of optically active *p*-bromobenzenesulfonate. Pure 1-methyl-2-*exo* acetate (3b),  $[\alpha]^{25}_D +9.20^\circ$  (*c* 5.2, chloroform), was heated at 100° for 8 hr in the simulated solvolysis solution. The usual work-up gave back pure 3b,  $[\alpha]^{25}_D +8.70^\circ$  (*c* 6.5, chloroform), a 6% loss of optical activity. Reduction of the acetate thus obtained with lithium aluminum hydride gave the corresponding alcohol which contained less than 0.5% tertiary alcohols 5b-OH or 10-OH.

Pure *t*-*endo* acetate 10-OAc,  $[\alpha]^{25}_{365} -51^\circ$  (*c* 4.9, chloroform), was heated for 8.0 hr at 100° in the simulated solvolysis solution. The reaction mixture was worked up as in the acetolysis experiment. The acetate after bulb-to-bulb distillation (0.03 mm) was analyzed on column N and found to contain 7% *t*-*exo* acetate 5b-OAc and just a trace of 1-methyl-2-*exo* acetate 3b. The specific rotation was  $[\alpha]^{25}_{365} -47^\circ$  (*c* 5.1, chloroform), a loss of 8.4% of the original optical activity. Since *t*-*exo* acetate 5b-OAc of the same relative configuration has the same sign of rotation, albeit only about 10% of the value of 10-OAc, a small amount of the *t*-*endo* acetate 10-OAc might also be racemized.

Similarly, pure *t*-*exo* acetate 5b-OAc,  $[\alpha]^{25}_D -1.67^\circ$ ;  $[\alpha]^{25}_{365} -5.29^\circ$  (*c* 4.9, chloroform), was subjected to the simulated solvolysis conditions for 8.25 hr at 100°. The distilled product was analyzed on column L and shown to contain 58.7% starting material 5b-OAc.

The acetate mixture was reduced with lithium aluminum hydride to alcohols in the usual manner. The alcohol mixture, when analyzed on column L, contained 22.9% 1-methyl-2-*exo* alcohol 3b-OH. The calculated concentration of the *t*-*endo* alcohol 10-OH was therefore 18.4%. The specific rotations of the alcohol mixture were:  $[\alpha]^{25}_D +1.79^\circ$ ;  $[\alpha]^{25}_{365} +4.55^\circ$  (*c* 6.0, chloroform). The unfractionated secondary acetate mixture obtained from the separation of the tertiary alcohols from the acetolysis products was subjected to the simulated solvolysis conditions for 10 hr at 100°.

The isolated acetate mixture was unchanged in composition as determined on capillary vpc columns L and N. No tertiary related material was detected (less than 0.1% of the total mixture would be observable). The specific rotation was unchanged from that of the original.

**Acetolysis of 3-*exo*-Methyl-2-*endo*-norbornyl *p*-Bromobenzenesulfonate in Acetic Acid-O-D.** Acetic acid-O-D was prepared from 99.8% deuterium oxide and slight excess of acetic anhydride by stirring at room temperature for 24 hr and distillation. A sample of 5.74 g (16.6 mmoles) of the pure *p*-bromobenzenesulfonate was added to 80 ml of acetic acid-O-D containing 3.22 g (39.3 mmoles) of sodium acetate. The reaction mixture was stirred at 100° for 10.0 hr and worked up in the usual manner. Analysis of the acetate mixture on capillary column L indicated the presence of 18.4% *t*-*endo* acetate and 1-methyl-2-*exo* acetate with 81.6% *t*-*exo* acetate in the "tertiary product mixture." The acetate mixture was reduced to alcohols with lithium aluminum hydride. The concentration of 1-methyl-2-*exo* alcohol 3b-OH was not determinable at that time because of capillary column degeneration. That some was present was evident from the preparative isolation. The tertiary alcohols were separated from the main solvolysis components on preparative vpc column E. The tertiary alcohol mixture contained 10.05 atom % excess deuterium as determined by the falling drop method, equivalent to 1.4 deuterium atoms per molecule. The components with longer retention time contained less than 0.03 deuterium atom per molecule. Deuterium analyses by the falling drop method were performed by Mr. J. Nemeth, Urbana, Ill.

**Acetolysis of 3-*exo*-Methyl-2-*endo*-norbornyl-*p*-Bromobenzenesulfonate in the Presence of 2-*exo*-Methyl-2-*exo*-norbornyl Acetate in Acetic Acid-O-D.** About 0.14 g (1.1 mmoles) of *t*-*exo* acetate 5b-OAc, 0.074 g (0.9 mmoles) of sodium acetate, and 0.13 g (0.37 mmoles) of *p*-bromobenzenesulfonate were added to 2.0 ml of dry acetic acid-O-D and heated at 100° for 10.0 hr. The usual work-up yielded acetates which were reduced to alcohols with lithium aluminum hydride. The tertiary alcohol mixture was separated from the alcohol mixture of longer retention time on column E and analyzed by the falling drop method. There was 12.70 atom % excess deuterium present, equivalent to 1.78 deuterium atoms per molecule. Since the tertiary products from the solvolysis of the *p*-bromobenzenesulfonate normally amount to only ca. 3% of the total mixture, the tertiary alcohols isolated from this particular run would be expected to be contaminated by only 1% of solvolysis product. Thus, deuterium incorporation clearly can occur after the formation of tertiary solvolysis product.

**Optically active 2-*exo*-methyl-2-*endo*-norbornanol (10-OH)** was prepared by adding an ether solution of norbornanone,  $[\alpha]_D -7.95^\circ$  (chloroform), to ethereal methylmagnesium bromide. The ketone was prepared by Jones oxidation<sup>13</sup> of active norbornanol.<sup>14</sup> The product 10-OH had infrared spectrum and retention times on vpc identical with those of an authentic sample<sup>16</sup> of the racemate. The alcohol had  $[\alpha]_D -6.45^\circ$ ,  $[\alpha]_{365} -17.4^\circ$  (*c* 4.3, chloroform).

Acetylation of the active alcohol with acetic anhydride in pyridine gave a quantitative yield of 10-OAc with infrared spectrum and retention times on vpc identical with those of the racemate. The sample, which contained 0.05% of 5-OAc, had  $[\alpha]_D -12.1^\circ$ ;  $[\alpha]_{365} -36.8^\circ$  (*c* 6.0–7.8, chloroform). Lithium aluminum hydride reduction regenerated 10-OH with undiminished rotation.

**Optically Active 2-*endo*-Methyl-2-*exo*-norbornanol (5-OH).** Following a procedure worked out in the racemic series,<sup>16</sup> a homogeneous sample of *t*-*endo* alcohol 10-OH,  $[\alpha]_D -12.1^\circ$  (chloroform), 3.00 g (0.024 mmoles), was stirred with 15 ml of concentrated hydrochloric acid for 2 hr at room temperature. The chloride was extracted with pentane and the organic solution washed with saturated brine. The solvent was distilled off in a 100-ml flask. The colorless residue was homogeneous on capillary columns L and N with the exception of a small amount of residual solvent.

The chloride was stirred at 95° with 35 ml of 1 *N* sodium hydroxide for 4 days. The cooled mixture was extracted four times with pentane; the combined organic layers were washed twice with saturated brine and dried over sodium sulfate, and the solvent was distilled off. The clear, colorless residue crystallized immediately on cooling to room temperature and was completely sublimed at 85° (10 mm). The yield was 2.36 g (80%) of material whose rotations were:  $[\alpha]^{25}_D +2.78^\circ$ ;  $[\alpha]^{25}_{365} +8.38^\circ$  (*c* 5.0–5.3, chloroform).

(35) H. C. Brown, N. R. Ayyangar, and G. Zweifel, *J. Am. Chem. Soc.*, **86**, 397 (1964).

(36) N. J. Toivonen, E. Siltanen, and K. Ojala, *Ann. Acad. Sci. Fennicae, Ser. AII*, No. 64 (1955).

**Optically Active 2-endo-Methyl-2-exo-norbornyl Acetate (5-OAc).** A homogeneous sample of the *t-exo* alcohol,  $[\alpha]_D^{25} +2.78^\circ$  (chloroform), was acetylated with excess acetic anhydride and pyridine at  $100^\circ$  for 13 hr in the usual manner and distilled to give a 94% yield of acetate 5-OAc, whose infrared spectrum and retention times on vpc were identical with those of authentic racemic material. Capillary vpc on columns L and N indicated 0.75% *t-endo* acetate 10-OAc was present; rotations:  $[\alpha]_D^{25} -1.01^\circ$ ;  $[\alpha]_{25}^{25} -3.36^\circ$  (c 5.2–5.4, chloroform). This acetate was reduced with lithium aluminum hydride in the usual manner to give alcohol 5-OH with the same rotation as that of the starting material. Analysis by capillary vpc on column L indicated the absence of 1-methyl-2-exo alcohol 3-OH where less than 0.05% could have been detected.

**Optically Active 1-Methyl-2-exo-norbornyl Acetate (3-OAc).** Following the method previously reported,<sup>11</sup> 6.08 g of *t-endo* alcohol 10-OH,  $[\alpha]_D^{25} -6.45^\circ$  (chloroform), was solvolyzed in acetic acid-sulfuric acid for 1.0 hr at  $98^\circ$ . Under these conditions, a few per cent each of *t-exo* acetate 5-OAc and *t-endo* acetate 10-OAc were present in addition to 3-OAc. Preparative vpc on column D using a Wilkens Autoprep 700A with automatic 60- $\mu$ l injections converted the *t-exo* acetate 5-OAc to olefins and cleanly separated the desired product 3-OAc from the *t-endo* acetate 10-OAc. Distillation of the purified acetate separated it from the eluted column packing and gave 4.08 g (52%) of material whose infrared spectrum and retention times on vpc were identical with those of authentic racemic material. Capillary vpc on column N indicated a total of less than 0.2% of impurities; rotations:  $[\alpha]_D^{25} +9.29^\circ$ ;  $[\alpha]_{25}^{25} +28.0^\circ$  (c 5.2–5.4, chloroform).

**Optically Active 1-Methyl-2-exo-norbornanol (3-OH).** The above acetate,  $[\alpha]_D^{25} +9.29^\circ$ , 0.722 g (4.29 mmoles), was reduced with 0.16 g of lithium aluminum hydride in the usual manner. Complete sublimation of the crude residue yielded 0.47 g (87%) of colorless, crystalline alcohol 3-OH. The infrared spectrum and retention times on vpc were identical with those of pure, racemic material prepared in a similar manner; rotation:  $[\alpha]_D^{25} +0.21^\circ$ ;  $[\alpha]_{25}^{25} -2.11^\circ$  (c 5.8–5.9, chloroform).

The alcohol recovered from the rotations was converted to the acetate with excess pyridine and acetic anhydride at  $100^\circ$  for 24 hr to give product with a rotation identical with that of the starting material.

**2-endo-Methyl-2,3-*cis*,*exo*-norbornanediol (14).** A sample of 2-methyl-2-norbornene<sup>17</sup> (0.20 g) was dissolved in 25 ml of dry ether. A stirred solution of 0.50 g of osmium tetroxide in 25 ml of ether was cooled to  $0^\circ$ , protected by a drying tube, and the olefin solution was added dropwise from a pressure-equalizing dropping funnel. A black solid precipitated during the addition; afterwards the mixture was allowed to stir overnight at room temperature. The black osmate ester was collected by filtration and added to a reaction flask containing 5.0 g of sodium sulfite, 25 ml of ethanol, and 25 ml of water. After heating at reflux for 1 hr on the steam bath, this mixture was filtered, and the filtrates were concentrated to dryness at the aspirator. The solid residue was extracted nine times with methylene chloride, and the organic extracts were combined and dried over magnesium sulfate. After filtration, the solvent was evaporated at the aspirator, leaving a greenish oil which distilled bulb to bulb to give a waxy solid.

This material exhibited an intense, broad O-H band in the infrared as well as a small C=O band due to an unknown contaminant. The diol was characterized by its nmr, which showed a broad signal at  $\delta$  4.1 (2 H) assigned to the hydroxyl protons and a slightly broadened absorption at  $\delta$  1.3 (about 4 H). Superimposed on the  $\delta$  1.3 absorption was a sharp singlet due to the methyl group, deshielded by the *gem*-hydroxyl function.

**Rearrangement of 2-endo-Methyl-2,3-*cis*,*exo*-norbornanediol (14).** A round-bottomed flask was charged with 4 ml of concentrated sulfuric acid and cooled to  $-8^\circ$  in an ice-salt bath. The cold solution was stirred rapidly with a magnetic apparatus, and 0.040 g of the solid diol 14 was added and allowed to stir in the acid for 10 min. After this time the yellow reaction mixture was poured onto cracked ice and extracted three times with pentane. The pentane was washed four times with saturated brine and dried over sodium sulfate. Careful removal of the solvent left about 30 mg of material which showed only one peak on capillary vpc column N-1, identical in retention time with 3-endo-methyl-2-norbornanone (15b). Control experiments showed that (1) less than 0.03% of the *exo*-methyl epimer could have been detected, and (2) both epimeric ketones were stable under the reaction conditions.

## Studies on the Molecular Geometry of the Norbornyl Cation.

### I. The Synthesis and Acetolysis of the *exo*- and *endo*-4,5-*exo*-Trimethylene-2-norbornyl *p*-Toluenesulfonates

E. J. Corey and Richard S. Glass

*Contribution from the Department of Chemistry, Harvard University, Cambridge, Massachusetts 02138. Received January 3, 1967*

**Abstract:** 4,5-*exo*-Trimethylene-2-norbornene (10) has been synthesized from a monosubstituted cyclopentadiene 9 using an intramolecular Diels-Alder reaction, and from this intermediate *exo*- and *endo*-4,5-*exo*-trimethylene-2-norbornyl *p*-toluenesulfonates (11, R = Ts, and 16, R = Ts) have been prepared. These sulfonates undergo acetolysis ( $25^\circ$ ) at relative rates of 8.6:1. The ratio of rate constants ( $25^\circ$ ) for acetolysis of the *exo*-sulfonate 11, R = Ts, and 2-*exo*-norbornyl *p*-toluenesulfonate is 1:85, whereas the corresponding ratio for the *endo*-sulfonate 16, R = Ts, and 2-*endo*-norbornyl *p*-toluenesulfonate is 1:2.5. The depressed rate for the tricyclic *exo*-sulfonate 11, R = Ts, relative to 2-*exo*-norbornyl *p*-toluenesulfonate is readily explained in terms of bridging of carbon in the transition state for ionization, but seems to be contrary to expectations based on ionization to a localized (classical) carbonium ion. Thus, the present results favor the *bridged-ion* mechanism for acetolysis of 2-*exo*-norbornyl arene-sulfonates.

A large body of data relating to the solvolysis reactions of various bicyclo[2.2.1]heptanes holding leaving groups such as halide or arenesulfonate at  $C_2$  is now available.<sup>1,2</sup> It is clear, especially from ex-

tensive investigations of the parent 2-norbornyl series, that these reactions exhibit characteristics which sharply differentiate them from simple aliphatic or monocyclic

(1) For an excellent recent review see G. D. Sargent, *Quart. Rev.* (London), **20**, 301 (1966).

ogs. These properties, due in large part to special features of the norbornyl cation,<sup>3</sup> include<sup>1,4-9</sup> (1) extraordinary ease of Wagner–Meerwein rearrangement of C<sub>1</sub> from C<sub>1</sub> to C<sub>2</sub> (as compared with other reaction paths); (2) dependence of reactivity on orientation, specifically, generally higher solvolysis rates for 2-*exo* derivatives as compared with the corresponding 2-*endo* compounds; and (3) extraordinarily specific formation of *exo*-substitution products arising from 2-*exo*-norbornyl derivatives. Similar behavior has been noted for a number of methyl-substituted norbornyl derivatives.<sup>1,5</sup> These distinctive characteristics of the norbornyl cation have been interpreted by some<sup>1,4,5</sup> in terms of a mechanism in which ionization is assisted by the rearrangement of C<sub>1</sub> from C<sub>1</sub> to C<sub>2</sub> to lead directly to an intermediate bridged ion (1) (*bridged-ion mechanism*), while others<sup>10-12</sup> have taken the view that the available data can be explained on the basis of rapidly rearranging localized norbornyl ions 2 (*classical-ion mechanism*). Additional evi-

which can serve to exclude one of these alternatives is clearly desirable. One possible approach toward this end is the detection of positive charge at C<sub>1</sub> or C<sub>2</sub> in the transition state using kinetic measurements with substrates having electron-supplying groups at these centers. Although studies have been carried along these lines,<sup>1,13,14</sup> they have not yielded the type of results which allow an unambiguous decision between the two theories. Another way of distinguishing between bridged-ion and classical-ion mechanisms is made possible in principle by the fact that the transition states for these paths should involve different geometries of the ring system. This paper describes the results of a part of an investigation aimed at revealing more fully the molecular geometry of the cationic species which intervene in the ionization reactions of 2-norbornyl *p*-toluenesulfonates. In general, a reasonable test for such a test could be the introduction of a bridge (or a set of bridges) into the bicyclo[2.2.1]heptane system in such a way as to produce either a large increase or decrease in total strain for the ring system upon migration of C<sub>1</sub> from C<sub>1</sub> to C<sub>2</sub> while at the same time preserving to a maximum extent for the initial and rearranged structures the exact geometry of the bicyclo[2.2.1]heptane part and also the exact

environment of groups at the *exo* and *endo* orientations at C<sub>2</sub>.

Before describing the specific molecular system which we have studied, a general consideration of the effect of Wagner–Meerwein rearrangement on the various positions of the norbornyl skeleton is appropriate. Let the various types of ring atoms in structure 3 be represented by descriptive letters as follows: common atoms 1 and 4 as *c* and *c'*, methano bridge as *m*, ethano bridge members as *e*<sub>1</sub>, *e*<sub>1</sub>' for the bridge bearing the leaving group, and *e*<sub>2</sub>, *e*<sub>2</sub>' for the other. After Wagner–Meerwein rearrangement of carbon, these atoms assume the locations indicated in 4. It will be noted that only two atoms, *c'* and *e*<sub>2</sub>', are both unchanged in type and

remote from the leaving and entering groups and also that *exo*- and *endo*-substituent interconversion occurs at *e*<sub>2</sub>'. Therefore, if a chain of atoms is added to join *c'* and *exo-e*<sub>2</sub>' in 3 with establishment of a new ring, the rearrangement 3 to 4 will produce a *stereoisomeric* system, in principle of different energy, without any essential interference with the environment of the leaving or entering groups. In the specific case of a trimethylene bridge, the stereoisomer *c'*-(CH<sub>2</sub>)<sub>3</sub>-*e*<sub>2</sub>'(*exo*) (5) can be formed with only a minor amount of additional angle strain. In contrast, the stereoisomer *c'*-(CH<sub>2</sub>)<sub>3</sub>-*e*<sub>2</sub>'(*endo*) (6) is formed with much angle strain in addition to the norbornyl strain. Crude estimates of

the difference in strain energy between 5 and 6 (principally angle strain) have been made in two different ways. In the first, the angle strain formula of Westheimer<sup>15</sup> has been used, taking into account only the distortions of C–C–C angles and using the values for ring angles as measured from (a) Cenco Peterson molecular models and (b) Fieser–Dreiding molecular models; this gave strain energy differences of (a) 7.2 kcal/mole and (b) 8.1 kcal/mole, with the likelihood that both estimates are too high<sup>15</sup> rather than too low. The second way for estimation of strain energy differences rests upon the recognition of 5 and 6 as derivatives of *cis*- and *trans*-pentalane, respectively. The ring systems of 5 and 6 can be formed by the joining of atoms in the hypothetical *cis*- and *trans*-pentalane derivatives 7 and 8. Simulation of the ring closure of

(15) F. H. Westheimer in "Steric Effects in Organic Chemistry," M. S. Newman, Ed., John Wiley and Sons, Inc., New York, N. Y., 1956, p 533 et seq.

Figure 1.

7 and 8 with the above-named types of models indicates that the increase in angle strain upon ring closure is 10–20% greater with 7 than with 8, which probably amounts to a difference of 0.5–1 kcal/mole.<sup>16</sup> This would roughly be offset by changes in torsional strain from 7 and 8 to 5 and 6, and, therefore, it appears that the difference in strain energy between 5 and 6 should be approximately the same as for *cis*- and *trans*-pentane systems, i.e., ca. 6–7 kcal/mole.<sup>17</sup>

Thus, there can be little doubt that 5 is substantially less strained than the isomer 6. This is also obvious simply by inspection of models which reveals additionally that the process of Wagner–Meerwein rearrangement of 5 to 6 results in a steady increase in strain. Therefore, it would be expected that if ionization leads to *bridging* in the transition state for solvolysis of 2-*exo*-norbornyl *p*-toluenesulfonate, the *p*-toluenesulfonates corresponding to 5 and 6 should react more slowly and more rapidly, respectively. On the other hand, the solvolysis rates for the three *endo*-*p*-toluenesulfonates should all be approximately the same, since presumably there should be little or no bridging of C<sub>6</sub> in the transition state and also no other differences for the three cases (e.g., steric acceleration or steric interference<sup>10–12</sup> to ionization should be the same). A reasonable prediction on the basis of the *classical-ion mechanism* is that the rates of solvolysis of the *exo*-*p*-toluenesulfonates 5 and 6 should be essentially the same as for the 2-*exo*-norbornyl case and, similarly, that the rates for the *endo*-*p*-toluenesulfonate isomers of 5 and 6 should be approximately the same as 2-*endo*-norbornyl.

It should be noted that the C<sub>1</sub>–C<sub>7</sub>–C<sub>3</sub> angle in 5 and 6 as observed in models appears to have the value which is normal for the simple bicyclo[2.2.1]heptane ring system (further evidence on this point appears in the following section). The number of carbons in the extra bridge connecting c' and e<sub>2</sub>' in 5 and 6 appears to be optimal for the purposes of revealing the molecular geometry of the norbornyl cation; fewer carbons would introduce too much strain and perturbation of the bicyclo[2.2.1]heptane system in *both* the *exo*- and *endo*-bridged structures, whereas a larger number of bridge atoms (>3) would diminish the differential strain be-

(16) A total closure strain energy from 7 and 8 to 5 and 6, respectively, is probably somewhat less than the strain energy of norcamphor (ca. 6 kcal/mole); see K. Alder and G. Stein, *Ber.*, **67**, 613 (1934); G. Becker and W. A. Roth, *ibid.*, **67**, 627 (1934); R. P. Linstead, *Ann. Rept.* (London), **32**, 315 (1935).

tween the *exo*- and *endo*-bridged structures to too a value.

## Synthetic Studies

The synthesis of 4,5-*exo*-trimethylene-2-*exo*-bornyl *p*-toluenesulfonate was accomplished in steps as outlined in Figure 1. Alkylation<sup>18</sup> of pentadienylsodium by 5-bromo-1-pentene produced a mixture of monosubstituted cyclopentadienes; the substituent principally at C<sub>1</sub> and C<sub>2</sub> as indicated by nmr measurements. When a dilute solution of the mixture of  $\Delta^4$ -pentenylcyclopentadienes 9 was heated with *n*-butylamine as solvent, 4,5-*exo*-trimethylnorbornene (10) was produced in good yield. The structure of the product from this reaction was indicated by physical, analytical, and chemical data. The alternative nonstereoisomeric internal Diels structure 13 could be excluded from consideration on the basis of the nmr spectrum of the product which exhibited a sextet consistent with the AB part of an ABX<sub>2</sub> centered at 6 ppm<sup>21,22</sup> due to two olefinic protons in broad band due to a *single* bridgehead (and allylic) proton at 2.8 ppm,<sup>23</sup> and the remaining aliphatic protons (found 11.0) between 2.0 and 1.0 ppm. Structure 13 can also be excluded from the nmr spectra of transformation products of 10, e.g., the *exo*-2,3-*endo*-2,3-epoxide and also on the basis of chemical data. The chemical evidence which excludes the structure stereoisomeric with 10 but having a 4,5-*endo*-trimethylene bridgehead is presented below.

Hydroboration of 10 with disiamylborane<sup>24,25</sup> produced a mixture of the alcohols 11, R = H, and 12, R = CH<sub>3</sub>, in a ratio of 92:8. The same alcohols were also produced using diborane as the reagent for hydroboration; the process was less useful for synthesis, since the products 11, R = H, and 12, R = H, were formed in a ratio of ca. 3:1; further, a third isomeric alcohol was produced in certain runs evidently because of use of more boron trifluoride than required for the generation of diborane reagent from sodium borohydride. The alcohol 11, R = H, was readily obtained from the 92:8 mixture *via* the crystalline 3,5-dinitrobenzoate ester. The crystalline alcohol so purified was converted to the crystalline *p*-toluenesulfonate 11.

11, mp 66.5–68°, by exposure to *p*-toluenesulfonic acid in pyridine. Oxidation of the alcohol

= H, by chromic acid afforded the corresponding ketone 15 (carbonyl absorption  $1749\text{ cm}^{-1}$ ,  $5.72\text{ }\mu$  in  $\text{CHCl}_3$ ), which was reduced with sodium borohydride in ethanol to yield the crystalline *endo* epimer of 11, 11, R = H (16, R = H). Reaction of 16, R = H, with toluenesulfonyl chloride gave the corresponding *p*-toluenesulfonate 16, R = Ts, mp  $50\text{--}51.5^\circ$ .

The nmr spectra<sup>22</sup> of the *exo* compounds 11, R = H, 11, R =  $\text{CH}_3\text{CO}$ , exhibit ROCH< proton resonance as a doublet of doublets centered at 3.88 and 4.23 ppm, respectively, whereas the nmr spectra of the compounds 16, R = H, and 16, R =  $\text{CH}_3\text{CO}$ , exhibit the ROCH< as much more complex multiplets centered at 4.23 and 4.98 ppm, respectively. Similarly, the toluenesulfonate 11, R = Ts, exhibits a ROCH< resonance as an overlapping doublet of doublets (pseudo-quartet) centered at 4.57 ppm, and the corresponding resonance in 16, R = Ts, is a broad, complex multiplet centered at 4.80 ppm. The more complex splitting observed with the derivatives of 16 as compared with those of 11 indicate additional coupling of *ca.* 3 cps; therefore, the adjacency of a bridgehead proton to the alcoholic function at C<sub>2</sub> rather than C<sub>3</sub> confirms the assignment which follows from the known orientational tendencies of disiamylborane in addition to unsymmetrically substituted olefins.<sup>24,25</sup> Hydroboration would also be expected to produce *exo* rather than *endo* alcohols, and this too is supported by the nmr data, since resonance for *exo*-ethanol protons occurs at lower field than for *endo*-ethanol protons in norbornane derivatives with characteristic differences in chemical shift of 0.3–0.6 ppm.<sup>26–29</sup> The configuration for 16, R = H, also follows from the configuration of this alcohol by borohydride reduction of the corresponding ketone 15.

Oxidation of the tricyclic olefin 10 with monomeric manganic acid in ether produced the *exo*-2,3-oxide in good yield. The nmr spectrum of this substance is completely consistent with structure 17. The protons attached to the epoxide ring give rise to a sharp doublet at 2.79 ppm and a broadened doublet at 2.96 ppm; a bridgehead hydrogen is responsible for a broad doublet at 2.42 ppm (*one proton only*), and a doublet at 4.1 ppm is clearly assignable to the 7-*anti* proton.<sup>30</sup> Reaction of the epoxide 17 with lithium aluminum hydride produced three isomeric alcohols, 11, R = H, 11, R = H, and 14 in a ratio of 33:63:4, whereas the reaction of lithium aluminum hydride–aluminum chloride produced only 11, R = H, and 14 (ratio 24:76). The rearranged alcohol 14 must arise *via* a Wagner–Meerwein process which becomes more important than the competing process, SN2 attack by hydride, with the more acidic “mixed hydride”<sup>31</sup> as compared with lithium aluminum hydride. The rearrangement can be explained (without regard for detail) as follows.

The occurrence of this rearrangement indicates clearly that the trimethylene bridge in 17 (and hence in 10, etc.) must be *c'*-*exo*-*e*<sub>2</sub>' and not *c'*-*endo*-*e*<sub>2</sub>'. The structure of 14 follows from physical and chemical data, including oxidation to a ketone which must possess the oxo function at the methano bridge, since the carbonyl stretching band is found at  $5.63\text{ }\mu$  in the infrared.<sup>32</sup> The formation of 14 from the tricyclic olefin 10 by reaction with mixtures of diborane and boron trifluoride followed by oxidation with alkaline hydrogen peroxide is a most interesting reaction which is deserving of further study. At present we can only speculate as to mechanism; one possibility is a process such as the following in which boron trifluoride (not shown) is coordinated (hydrogen bond) to a borane hydrogen.<sup>33</sup> This rearrangement also requires that the starting

tricyclic olefin be formulated as 4,5-*exo*-trimethylene-2-norbornene (10) rather than the *endo* isomer. In fact, we have observed a whole series of such rearrangements which proceed with remarkable ease (even more readily than with the parent norbornyl system); some of these are outlined in a later section.

Independent evidence for the structure 10 as opposed to the *endo*-trimethylene formulation comes from the reaction of the oxide 17 with lithium diethylamide, which leads to a saturated tetracyclic alcohol which can be assigned structure 18 on the basis of physical and chemical data, much of which is discussed below. The mechanism of this reaction would appear to be analogous to other base-catalyzed rearrangements of 1,2-epoxides<sup>34,35</sup> which appear to proceed *via*  $\beta$ -alkoxy carbenes. The formation of 18 from such a carbene 19 appears only to be possible if the trimethylene bridge in the starting oxide 17 is *exo*.

A number of experiments directed at the synthesis of 4,5-*endo*-trimethylene-2-norbornyl derivatives (6, X = *endo*- or *exo*-OH) have been carried out, but members of this series have not been obtained to date. Synthetic efforts to produce these compounds are continuing.

**Acetolysis Studies.** Rates of acetolysis of 4,5-*exo*-trimethylene-2-*exo*-norbornyl *p*-toluenesulfonate (11, R = Ts) and 4,5-*exo*-trimethylene-2-*endo*-norbornyl *p*-toluenesulfonate (16, R = Ts) were measured at several temperatures in anhydrous acetic acid containing sodium acetate using the spectrophotometric method of Swain and Morgan,<sup>36</sup> which depends on the difference in intensity of absorption in the region 260–280 m $\mu$  between *p*-toluenesulfonate ion and *p*-toluenesulfonate esters. First-order kinetics were observed for both 11 and 16, R = Ts, and the infinity readings were found to be stable. The kinetic results are summarized in Table I, which also presents data<sup>37</sup> on 2-*exo*- and 2-*endo*-norbornyl *p*-toluenesulfonates for comparison.

<sup>a</sup> These runs made with 0.010 *M* sodium acetate and <0.005 *M* substrate. <sup>b</sup> Calculated from data at other temperatures. <sup>c</sup> Taken from ref 37 (also calculated from data at other temperatures).

The ratio of acetolysis rate constants for the *exo*- and *endo*-tricyclic *p*-toluenesulfonates 11, R = Ts, and 16, R = Ts, is calculated as 8.6 at 25° and 6.8 at 82.6°; these are much smaller than the *exo*:*endo* ratio for the 2-norbornyl system, *e.g.*, 280 at 25°. The rate of acetolysis of the *exo*-tricyclic *p*-toluenesulfonate 11, R = Ts, is much smaller than that for 2-*exo*-norbornyl, the relative rates at 25° being 1:82.5, respectively. In contrast, the acetolysis rates of the *endo*-tricyclic *p*-toluenesulfonate 16, and 2-*endo*-norbornyl are very similar, the ratio at 25° being 1:2.5, respectively.

The lower rate of acetolysis of 4,5-*exo*-trimethylene 2-*exo*-*p*-toluenesulfonate (11, R = Ts) as compared with 2-*exo*-norbornyl might, for some obscure reason, be due to a difference in the tendency of the corresponding ion pairs to suffer acetolysis relative to internal return rather than to a difference in rates of ionization. This would seem unlikely *a priori*, but it also seems inappropriate because of data which have been obtained on the effect of added inert salt on the acetolysis of 11, R = Ts. The acetolysis rate constants observed for 11, R = Ts, in glacial acetic acid containing 0.01 *M* sodium acetate at 67.88° and varying molar concentrations of lithium perchlorate are: 76 (10<sup>-6</sup>) at 0.00 *M* LiClO<sub>4</sub>, 89.4 (10<sup>-6</sup>) at 0.0098 *M* LiClO<sub>4</sub>, 180 (10<sup>-6</sup>) at 0.05 *M* LiClO<sub>4</sub>, and 320 (10<sup>-6</sup>) at 0.100 *M* LiClO<sub>4</sub>. The evidence from other systems would tend to argue that as the concentration of LiClO<sub>4</sub> is increased to *ca.*

0.015 *M*, most of the internal return which can be prevented at all by this salt has been nullified (presumably this is return from "solvent-separated" ion pairs).<sup>38-40</sup> Under these conditions the rate of acetolysis of 11, R = Ts, is still very much less than that of 2-*exo*-norbornyl. Further, the type of salt effect noted for the acetolysis of 11, R = Ts, does not appear to provide any basis for supposing an abnormal reluctance for "solvent-separated ion pairs"<sup>38-40</sup> to react with solvent. It should also be noted that an argument can be given<sup>41</sup> that acetolysis of 2-*exo*-norbornyl *p*-bromobenzenesulfonate probably does not occur directly from the "intimate ion pair," *i.e.*, from the type of ion pair which is not subject to anion exchange with perchlorate. If such acetolysis could occur with 2-*exo*-norbornyl but not with the *exo*-tricyclic analog 11, R = Ts, the lower rate of the latter might conceivably be rationalized (quite unconvincingly) along such lines.

The major product from acetolysis of the tricyclic *exo*-*p*-toluenesulfonate 11, R = Ts, and the tricyclic *endo*-*p*-toluenesulfonate 16, R = Ts, was in each case the tricyclic *exo*-acetate 11, R = CH<sub>3</sub>CO, which was formed to the extent of 91.5 and 92% of the total mixture of products, respectively. At least two more acetates were detected along with the major product from both 11, R = Ts, and 16, R = Ts; in each case these constituted *ca.* 4% of the total mixture. These were not identified due to the difficulty of separation from each other and from 11, R = CH<sub>3</sub>CO.<sup>41</sup> The vpc analyses indicated that one of the minor acetates could be the tricyclic *endo*-acetate 16, R = CH<sub>3</sub>CO, on the basis of correspondence of retention times. However, additional investigation of this possibility is required and is planned. Two hydrocarbons were also formed in the acetolysis of 11, R = Ts, and 16, R = Ts, in a total yield of *ca.* 4%. The preponderant hydrocarbon exhibited the same vpc behavior as the tricyclic olefin 10.

## Discussion

The results of this study are most simply interpreted in terms of the *bridged-ion mechanism* for the acetolysis of 2-*exo*-norbornyl sulfonates. This mechanism should lose much or all of its driving force in the case of the tricyclic *exo*-*p*-toluenesulfonate, 11, R = Ts (see introductory section), and so the slow acetolysis of this substrate relative to norbornyl is readily explained (and, in fact, was to be expected). In comparison, but also as predicted on the basis of the Winstein-Trifan arguments, 2-*endo*-norbornyl *p*-toluenesulfonate and the tricyclic *endo*-*p*-toluenesulfonate 16, R = Ts, for which bridging is not to be expected in the transition state for ionization on stereochemical grounds, show quite similar reactivity. Here it should be noted that the carbonyl stretching frequencies for 4,5-*exo*-trimethylenenorcamphor (15) and norcamphor, measured under the same conditions (CCl<sub>4</sub> solution) with a Cary-White Model 90 infrared spectrometer (with polystyrene for calibration), were found to be 1749 and 1750 cm<sup>-1</sup>, respectively. This would indicate

ferences in angle strain at C<sub>2</sub> cannot be responsible for the different acetolysis rates observed in the fionate series and also that the *endo*-sulfonates should be approximately the same.<sup>42</sup> *Classical-ion mechanism*, in a straightforward ionization, leads to the expectation that in acetolysis of 2-norbornyl  $\cong k(11, R = Ts)$  and  $k(2\text{-endo-norbornyl}) \cong k(16, R = Ts)$ . This is *not* the case, and it does not seem to be any obvious reason for the different reactivity of the tricyclic *exo-p*-toluenesulfonates, R = Ts, keeping in mind the data on the *endo*-sulfonates. Substitution of simple alkyl at C<sub>4</sub> and/or C<sub>7</sub> could not be expected to produce a differential in the reactivities of 11 and 16, R = Ts, in a *classical-ion mechanism*, especially since the effect of methyl hydrogen by methyl at these positions in the norbornyl series is small either with regard to *endo* rates alone or the *endo* rates alone.<sup>43</sup> The arguments which have been given in support of the *classical-ion mechanism*<sup>10-12</sup> include (1) greater steric hindrance to *endo* relative to *exo* group ionization to give the observed relative solvolysis rates of *exo*- and *endo*-norbornyl derivatives and (2) some kind of effect which causes *endo* attack by solvent on the bridged cation to be much slower than *exo* attack. There is little in these suggestions which helps to explain the results obtained in the present study.

We regard our results as providing clear support for the *bridged-ion mechanism* for solvolysis of 2-*exo*-norbornyl derivatives. However, it must be pointed out that confirmatory data from the study of the 4,5-trimethylene-2-norbornyl sulfonates is highly desirable.

There is no evidence available at present which allows assignment of mechanism for the acetolysis of cyclic *exo-p*-toluenesulfonate 11, R = Ts. It is obviously possible that a part or even all of this reaction follows the classical pathway for ionization; again, further study is in order.

The results reported here add further evidence that the bridged norbornyl cation is especially stabilized relative to the classical ion, but they provide no information as to the origin of that stabilization. One possibility deserves mention in this regard. Normally, for aliphatic cations,<sup>44</sup> Wagner-Meerwein rearrangements proceed with low activation energies, perhaps in the order of a few kcal/mole. Assuming that the bridged ion which intervenes during such rearrangements has an energy very close to that of the transition state, it seems that only a small degree of extra stabilization (perhaps 3-7 kcal/mole) would be needed in certain cases to render the bridged ion more stable than a classical ion. At least part of this extra stabilization could be available in the bridged norbornyl cation from relief of angle strain. In the bicyclo[2.2.1]heptane cation a number of bond angles are distorted from their normal values leading to considerable angle strain. Angles C<sub>1</sub>-C<sub>2</sub>-C<sub>3</sub> (ca. 95°), H-C<sub>1</sub>-C<sub>7</sub>, and H-C<sub>4</sub>-C<sub>7</sub> (8°) are especially strained.<sup>45</sup> Much of this strain

would be relieved in going to a symmetrically bridged ion with C<sub>6</sub>-C<sub>1</sub> and C<sub>6</sub>-C<sub>2</sub> distances ca. 1.70 Å (i.e., about 10% longer than a normal C-C single bond), and essentially all the strain would be relieved in a bridged structure with C<sub>6</sub>-C<sub>1</sub> and C<sub>6</sub>-C<sub>2</sub> distances of 1.8 Å (only ca. 20% longer than normal for C-C).<sup>46</sup> Since the angle strain in the bicyclo[2.2.1]heptane ring appears to be ca. 6 kcal/mole,<sup>46</sup> it is clear that considerable stabilization is available to the symmetrically bridged ion through relief of angle strain. Of course other factors may also contribute to the end result. For example, "I strain"<sup>47</sup> might destabilize the classical cation (C<sub>1</sub>-C<sub>2</sub>-C<sub>3</sub> angle ca. 104°) substantially. Finally, as is well known, the geometry of 2-*exo*-norbornyl derivatives is ideal for migration of C<sub>4</sub> to C<sub>2</sub> during the ionization process.

The only data currently at hand for which the *bridged-ion mechanism* does not provide a ready and cogent explanation, in our view, are those on the acetolysis of 1-aryl-2-*endo*- and 2-*exo*-norbornyl *p*-toluenesulfonates.<sup>48</sup> Using the Hammett equation,<sup>49</sup> it was found that the data on both *exo* and *endo* sulfonates were correlated better using  $\sigma^+$  constants rather than  $\sigma$  values of Brown and Okamoto<sup>50</sup> and further that the  $\rho$  values for the 2-*exo*- and 2-*endo*-sulfonates were similar and low; at 25°  $\rho_{exo} = -1.36$  and  $\rho_{endo} = ca. -1.14$ .<sup>48</sup> There may be simple explanations of these data; these are not apparent at present, however.

**Reactions of 4,5-*exo*-Trimethylenebicyclo[2.2.1]heptane Derivatives.** In this section we record certain transformations of the tricyclic olefin 10 and its 2,3-oxide 17 which are of interest in connection with the development of the chemistry of this interesting system and which also serve to confirm the structural assignments indicated in the foregoing discussion. The tricyclic olefin 10 reacts with a number of electrophiles with rearrangement by a process which can be depicted as follows.

For example, reaction of 10 with aqueous mercuric perchlorate produces after addition of chloride ion 20, E = HgCl, N = OH, reduction of which with sodium borohydride<sup>51</sup> affords the tertiary alcohol 21.<sup>52</sup>

(46) For reference it is interesting that the bridged and nonbridged B-H distances in diborane are 1.33 and 1.19 Å, respectively. See W. N. Lipscomb, "Boron Hydrides," W. A. Benjamin, Inc., New York, N. Y., 1963.

The nmr spectrum of 21 and the corresponding acetate indicate clearly that the hydroxyl function is tertiary. Hydrolysis of the *p*-toluenesulfonate 22 (from 12, R = H) in aqueous acetone containing calcium carbonate also leads to 21 cleanly. Interestingly, treatment of 21 with sulfuric acid produces 1-adamantanol.

Reaction of the tricyclic olefin 10 with bromine<sup>53</sup> gives a dibromide which is converted by heating with an aqueous suspension of silver oxide to the bromohydrin 20, N = OH, E = Br, which by further reaction with di-*n*-butyltin dihydride<sup>54</sup> yields the tertiary alcohol 21.

The *syn* relationship of N and E in the products of type 20 is assumed by analogy with the cases of stereospecific *exo* addition of various electrophilic reagents to norbornene. The diol 20, N = E = OH, is readily obtained by treatment of the epoxide 17 with acidic catalysts such as silica gel; chromic acid oxidation of this diol leads as expected to a keto tertiary alcohol (23) which shows characteristic bridge carbonyl absorption at 5.64  $\mu$ .

Along other lines, the tricyclic ketone 15 was converted by peracetic acid to the lactone 24 and thence by hydrolysis with base, oxidation with chromic acid, and subsequent reactions to a series of derivatives of the keto acid 25, R = H. The infrared and nmr spectra<sup>22</sup> of 24 and the derivatives of 25 provide convincing evidence for the structures of these substances and, in consequence, for the precursors 15 and 10. For example, the lactone 24 shows low-field resonance due to a single proton (>CHO) in the nmr spectrum at 4.72 ppm (apparent quintet) and carbonyl absorption at 5.71  $\mu$  (CCl<sub>4</sub>), and the ketonic carbonyl of the derivatives of 25 gives rise to absorption at 5.74  $\mu$  (CCl<sub>4</sub>) as expected for a cyclopentanone.

A series of transformations starting from the tetracyclic alcohol 18 is also of interest. Evidence for the constitution 18 for the tetracyclic alcohol comes (a) from the characteristic cyclopropyl CH absorption in the infrared at 3.28  $\mu$ <sup>55</sup> and in the near infrared at 1.676  $\mu$ ,<sup>56</sup> (b) the absence of olefinic CH peaks in the

nmr spectrum, and (c) oxidation by chromic acid to the corresponding ketone (26) which showed absorption in the infrared at 3.31  $\mu$  (cyclopropyl CH)<sup>55</sup> and 5.67 and 5.72  $\mu$  (*cf.* nortricyclanone carbonyl absorption at 5.66 and 5.70  $\mu$ ).<sup>57</sup> Reaction of the ketone 26 with hydrogen bromide in methylene chloride produced a bromo ketone which from the mode of formation<sup>58</sup> and spectroscopic data is formulated as 5-bromo-4,5-trimethylene-2-norbornanone (27). This bromo ketone affords by reduction either with zinc-acetic acid, di-*n*-butyltin dihydride in tetrahydrofuran, or hydrogen and palladium on charcoal in ethanol the tricyclic ketone 15 cleanly; none of the isomeric *endo*-4,5-trimethylene-2-norbornanone could be detected.

## Experimental Section

Melting points, determined using a Büchi melting point apparatus, are uncorrected. Infrared data were obtained with a Perkin-Elmer Infracord spectrophotometer, a Perkin-Elmer Model 137 sodium chloride spectrophotometer, a Perkin-Elmer Model 237 grating infrared spectrometer, and for high resolution a Cary-White Model 90 infrared spectrometer using polystyrene as a calibration standard. Near-infrared data were obtained using a Cary Model 14 spectrophotometer. Ultraviolet spectra were taken using a Cary Model 11 M ultraviolet spectrometer and a Cary Model 14 spectrophotometer. The nmr data were obtained at 60 Mc using a Varian Associates Model A-60 nmr spectrometer and are expressed as shift downfield from internal tetramethylsilane in parts per million. Vapor phase chromatography was performed using an F & M Model 300 unit with a thermal conductivity detector and an F & M Model 609 flame ionization unit. The mass spectra were recorded using a Consolidated Engineering Corp. Model 21-103 C mass spectrometer and an Associated Electrical Industries Ltd. Model MS-9 mass spectrometer. Microanalyses were performed by Alfred Bernhardt Mikroanalytisches Laboratorium, Mülheim (Ruhr), Germany, and Scandinavian Microanalytical Laboratory, Herlev, Denmark.

**$\Delta^4$ -Pentenylcyclopentadienes 9.** A 1-l., three-necked flask was equipped with a mechanical stirrer having a glass blade, a two-way stopcock to let in ammonia, a three-way stopcock for maintaining a nitrogen atmosphere, and a Y tube fitted with a pressure-equalized dropping funnel and a dewar condenser. Sodium metal (11.5 g, 0.501 g-atom) was placed in the flask under nitrogen and dissolved in distilled ammonia (500 ml).<sup>19</sup> The blue solution was cooled in a Dry Ice-acetone bath and stirred vigorously as dry, distilled cyclopentadiene (62 ml, 0.750 mole) was added dropwise from the pressure-equilibrated dropping funnel. As soon as the mixture became colorless, 5-bromo-1-pentene (74.5 g, 0.500 mole) was added over a 45-min period. The reaction mixture was cooled in a Dry Ice-acetone bath and stirred for 2.5 hr. After allowing the ammonia to evaporate, salt-water was added, and the aqueous mixture was extracted with ether. The ethereal layer was dried with anhydrous magnesium sulfate and filtered. The solvent was removed at room temperature with a water aspirator, and the yellow residue was distilled giving 57.9 g (86%) of the  $\Delta^4$ -pentenylcyclopentadienes (9): bp 50–53° (7 mm). The infrared spectrum<sup>22</sup> of the product showed C=C stretching absorption at 6.08 and 6.23  $\mu$ ; the nmr spectrum<sup>22</sup> showed olefinic proton peaks from 4.8 to 6.4 ppm (integrated ratio to upfield protons 5.7:8) and indicated that the mixture consisted largely of C<sub>1</sub> and C<sub>3</sub> substituted cyclopentadienes. Because of the reactivity of 9 no elemental analysis was performed. The product showed ultraviolet absorption at  $\lambda_{\max}$  248 m $\mu$  ( $\epsilon$  3200).

**4,5-*exo*-Trimethylene-2-norbornene (10).** A 300-ml, three-necked flask was equipped with a condenser, a three-way stopcock, a glass encased magnetized bar, and a pressure-equalized dropping funnel. Purified tri-*n*-butylamine (100 ml) was added to the flask under nitrogen, and the flask was placed in a silicone oil bath main-

at 200°. A solution of  $\Delta^4$ -pentenylcyclopentadienes 9 (0.112 mole) in tri-*n*-butylamine (100 ml) was added dropwise to solvent with stirring over a period of 1 hr. The cooled mixture was poured into ice-cold aqueous hydrochloric acid and extracted with two 150-ml portions of distilled trichlorofluoromethane (Freon 11). The combined organic layers were washed with dilute hydrochloric acid and then sodium carbonate and with anhydrous magnesium sulfate. The solvent was removed by distillation at atmospheric pressure through a column of silica gel, and the residue was distilled through a column of a reflux condenser through which water was passed at a rate so as to maintain good reflux. The residual yellow solid was distilled from lithium aluminum hydride, giving 9.7–14.3 g (70%) of tricyclic olefin 10, bp 64–65° (26 mm). The molecular weight determined by mass spectrometry was 134. The nmr spectrum of 10<sup>13</sup> exhibited peaks at 1–2 ppm (1H), a broad singlet at 2.12 ppm due to the single bridgehead proton, and a six-peak set (AB part of an ABX pattern, 2H) due to the two olefinic protons. The infrared spectrum<sup>12</sup> showed olefinic CH stretch at 3.0  $\mu$ , C=C stretch at 6.23 and 6.42  $\mu$ , and a *cis*-CH=CH out-of-plane deformation band at 14.18  $\mu$ .

A small amount (3–5%) of an isomeric impurity which requires further study could be detected in the crude product by vpc analysis. A typical sample of 10 was prepared by vpc.

Calcd for C<sub>10</sub>H<sub>14</sub>: C, 89.48; H, 10.57. Found: C, 89.48; H, 10.57.

**Synthesis of Tricyclic Olefin 10 with Diborane.** A solution of tricyclic olefin 10 (1.34 g, 10.0 mmol) in dry, distilled tetrahydrofuran (10 ml) was placed in a 25-ml, three-necked flask equipped with a glass stopper, a mercury sealed valve, and a glass tube with a side arm. The glass tube was connected to a diborane generator which consisted of a 25-ml, three-necked flask equipped with a magnetic stirring bar, a rubber serum cap, and a three-way stopcock. Distilled boron trifluoride etherate (780 mg, 5.5 mmol) and distilled diglyme (0.7 ml) were placed in the generator. The air in the entire assembly was displaced by nitrogen. The diborane, produced by dropwise addition of a 1 M solution of sodium borohydride in diglyme (2.75 ml, 2.75 mmol) by a syringe to the boron trifluoride etherate solution, was passed as a slow stream of nitrogen into the tetrahydrofuran solution of 10 (cooled in an ice bath). After completion of the addition of the sodium borohydride solution, the diborane-producing solution was heated at 70–80° for 1 hr, and then the reaction flask was disconnected from the generator. The reaction solution was allowed to stand 6 hr at 0° and 36 hr at room temperature. To the solution, 2.86 M sodium hydroxide (1.10 ml, 3.15 mmol) was added followed by 30% hydrogen peroxide (1.1 ml, 11 mmol). The reaction mixture was allowed to stand for 1 hr at 0° and for 2 hr at room temperature, poured into water, and extracted with ether. The etheral extracts were stirred for 1 hr with 5% palladium on charcoal, dried (MgSO<sub>4</sub>), concentrated, and distilled, giving 990 mg (70%) of a mixture of alcohols. The mixture was analyzed by vpc on a 12-ft 5% Carbowax 20M column and found to consist of 11 (70%), 12 (17%), and 14 (13%).

When run only 11, R = H (74%), and 12, R = H, were obtained, but an aliquot of this reaction mixture to which boron trifluoride etherate was added gave 14 in addition to these alcohols.

**Synthesis of Tricyclic Olefin 10 with Diamylborane.** In a dry, 100-ml flask equipped with a serum cap were placed 2-methyl-2-butene (23.1 g, 0.329 mole), dry, distilled diglyme (50 ml), and sodium borohydride (4.70 g, 0.124 mole) under nitrogen. The mixture was stirred vigorously and cooled in an ice bath as distilled boron trifluoride etherate (23.5 g, 0.166 mole) was added dropwise from a syringe over a period of 45 min. The mixture was allowed to stand at 0° for 15–18 hr. Tricyclic olefin 10 (5.52 g, 0.042 mole) dissolved in diglyme (5 ml) was added to the semisolid mixture. The mixture was stirred for 30 hr at 0° and for 24 hr at room temperature. The reaction mixture was oxidized by adding 3 N sodium hydroxide (50 ml) followed by dropwise addition of 30% hydrogen peroxide (50 ml). After stirring for 5 hr the mixture was diluted with water and extracted twice with ether. The etheral extracts were washed four times with cold water, dried with sodium bisulfite solution, and once again with water, dried with anhydrous magnesium sulfate, concentrated, and distilled, giving 3.84 g (62%) of a mixture of alcohols, bp 62–63° (0.02 mm). The mixture was analyzed by vpc and found to consist of 12 (8%), 11, R = H (92%). Part of this mixture of alcohols (0.912 g, 6.0 mmol) and 3,5-dinitrobenzoyl chloride (6.6 mmol) were heated in dry, distilled pyridine (6 ml) with stirring. The solution was stirred for 3.5 hr at room temperature, and the mixture was dissolved in benzene,

washed with cold, dilute hydrochloric acid (9.0 ml of concentrated HCl in 300 ml of water), water, and saturated sodium bicarbonate solution, dried (K<sub>2</sub>CO<sub>3</sub>), and concentrated, leaving 1.91 g (92%) of a mixture of esters. The mixture was recrystallized twice from *n*-hexane, yielding 1.31 g (70%) of the 3,5-dinitrobenzoate 11, R = H (NO<sub>2</sub>)<sub>2</sub>C<sub>6</sub>H<sub>3</sub>CO<sub>2</sub>, mp 121.5–122.5°;  $\lambda$  (CHCl<sub>3</sub>) 3.22, 3.39, 3.49, 5.81 (C=O), 6.15 (C=C), 6.50, 7.49, 7.82, 8.59  $\mu$ .

Anal. Calcd for C<sub>17</sub>H<sub>18</sub>N<sub>2</sub>O<sub>6</sub>: C, 58.96; H, 5.24; N, 8.09. Found: C, 58.96; H, 5.35; N, 8.10.

The purified 3,5-dinitrobenzoate of 11, R = H (1.23 g, 3.54 mmol), methanol (5.9 ml), and 5 N sodium hydroxide (2.9 ml) were refluxed under nitrogen for 1 hr. The mixture was added to water and repeatedly extracted with ether. The etheral extracts were dried with anhydrous potassium carbonate and concentrated, leaving 11, R = H, in quantitative yield, mp 45–49°.

The infrared spectrum of 11, R = H (neat), showed hydroxyl absorption at 2.96  $\mu$  (broad); the nmr spectrum (CDCl<sub>3</sub>) exhibited a doublet of doublets at 3.88 ppm due to >CHO (1H), a sharp peak due to OH at 2.88 ppm, a broad singlet due to bridgehead CH (1H) at 2.12 ppm, and many peaks due to the remaining protons at 2.0–1.0 ppm.

Anal. Calcd for C<sub>16</sub>H<sub>16</sub>O: C, 78.90; H, 10.59. Found: C, 78.62; H, 10.56.

The alcohol 12, R = H, was isolated as follows. The mother liquor from the first recrystallization of the mixture of 3,5-dinitrobenzoates of alcohols 11 and 12 was concentrated. Hydrolysis of the mixture of esters and preparative vpc of the mixture of alcohols gave 12, R = H: hydroxyl absorption at 2.65 and 2.8  $\mu$ ; nmr (CDCl<sub>3</sub>): 1.0–2.3 (multiplet, 14H), 2.65 (singlet, 1H), and 3.60 ppm (broadened doublet, *J* = 6.5 cps, 1H).<sup>23</sup>

Anal. Calcd for C<sub>16</sub>H<sub>16</sub>O: C, 78.90; H, 10.59. Found: C, 78.60; H, 10.56.

**exo-4,5-Trimethylene-2-exo-norbornyl *p*-Toluenesulfonate (11, R = Ts).** To a solution of the tricyclic *exo* alcohol 11, R = H (76.9 mg, 0.506 mmol), in dry, distilled pyridine (1.25 ml), *p*-toluenesulfonyl chloride (250.6 mg, 1.32 mmol) was added. The solution was allowed to stand for 24 hr at room temperature. Four drops of water were added, and the solution was allowed to stand for 0.5 hr without cooling. The solution was poured into water and ether, and the aqueous phase extracted again with ether. The combined extracts were washed with water, sodium bisulfate solution, and water again, dried (MgSO<sub>4</sub>), and concentrated, leaving 150 mg (97%) of 4,5-exo-trimethylene-2-exo-norbornyl tosylate (11, R = Ts), mp 66.5–68°;  $\lambda_{\text{max}}^{\text{NaOH, 0.01M NaOH}}$  262.3  $\mu$  ( $\epsilon$  554), 267.5  $\mu$  ( $\epsilon$  500), and 273.2  $\mu$  ( $\epsilon$  446). The infrared and nmr spectra<sup>23</sup> agreed with the assigned structure.

Anal. Calcd for C<sub>17</sub>H<sub>20</sub>O<sub>2</sub>S: C, 66.61; H, 7.24; S, 10.47. Found: C, 66.75; H, 7.09; S, 10.63.

**exo-4,5-Trimethylene-2-norbornanone (15).** To a stirred solution of tricyclic alcohol 11, R = H (152 mg, 1.00 mmol), in acetone (2.5 ml) cooled in an ice bath, oxidizing agent (6.68 g of chromium trioxide and 5.75 ml of concentrated sulfuric acid diluted to 100 ml of solution with water) was added dropwise. The addition was continued until the color of the reagent was not discharged within 0.5 hr at room temperature. The excess oxidant was destroyed with isopropyl alcohol. The mixture was diluted with water and repeatedly extracted with ether. The etheral extracts were washed with saturated aqueous sodium bicarbonate solution and water, dried with anhydrous potassium carbonate, and concentrated, leaving 143 mg (95%) of tricyclic ketone 15; the infrared spectrum showed  $\nu$  (CCl<sub>4</sub>) 1749 cm<sup>-1</sup>.

Anal. Calcd for C<sub>16</sub>H<sub>16</sub>O: C, 79.96; H, 9.39. Found: C, 80.13; H, 9.50.

To the tricyclic ketone 15 (24.3 mg, 0.162 mmol) dissolved in 95% ethanol (0.4 ml), a solution of acidic 2,4-dinitrophenylhydrazine (1.0 ml) reagent was added. The reaction mixture was allowed to stand for several hours at room temperature. Filtration of the mixture gave 48.1 mg (90%) of a yellow solid. Two recrystallizations from acetonitrile gave yellow crystals of the 2,4-dinitrophenylhydrazone of tricyclic ketone 15, mp 172–174°;  $\lambda$  (CHCl<sub>3</sub>) 2.97, 3.35, 6.17, 6.29, and 7.50  $\mu$ .

Anal. Calcd for C<sub>16</sub>H<sub>18</sub>N<sub>4</sub>O<sub>4</sub>: C, 58.17; H, 5.49; N, 16.96. Found: C, 58.14; H, 5.48; N, 17.13.

**exo-4,5-Trimethylene-2-endo-norborneol (16, R = H).** To a solution of the tricyclic ketone 15 (30.0 mg, 0.200 mmol) in methanol (1.0 ml) cooled in an ice bath was added sodium borohydride (37.1 mg, 0.981 mmol) dissolved in cold methanol (2.0 ml) with stirring over a period of 30 min. The solution was stirred at 0° for 1 hr and at room temperature for 2 hr. The mixture was poured into water and twice extracted with 2:1 *n*-pentane-methylene

chloride solution. The combined organic extracts were washed three times with water, dried ( $\text{MgSO}_4$ ), and concentrated, giving 29.7 mg (97%) of tricyclic *endo* alcohol 16,  $\text{R} = \text{H}$ . The solid was dissolved in *n*-pentane at room temperature and cooled to  $0^\circ$ . Recrystallization twice in this manner gave colorless crystals, mp  $56\text{--}58^\circ$ . The molecular weight determined mass spectrometrically was 152.1200 (calcd for  $\text{C}_{10}\text{H}_{16}\text{O}$ : 152.1201). The nmr spectrum<sup>22</sup> of 16,  $\text{R} = \text{H}$ , showed a multiplet (1 H) due to  $>\text{CHO}$  at 4.23 ppm, a sharp peak due to hydroxyl at 3.2 ppm, and many peaks due to the remaining protons at 0.85–2.4 ppm; the infrared spectrum showed the expected OH stretching absorption at 2.65 and  $2.95\ \mu$  in  $\text{CCl}_4$ .

*Anal.* Calcd for  $\text{C}_{10}\text{H}_{16}\text{O}$ : C, 78.90; H, 10.59. Found: C, 79.31; H, 10.65.

*p*-Toluenesulfonate 16,  $\text{R} = \text{Ts}$ . The *endo* tricyclic alcohol 16,  $\text{R} = \text{H}$  (39.4 mg, 0.259 mmole), dissolved in pyridine (0.65 ml) was allowed to react with *p*-toluenesulfonyl chloride (130.6 mg, 0.685 mmole) as described for the preparation of 11,  $\text{R} = \text{Ts}$ , giving 74.4 mg (96%) of a solid. Two recrystallizations from *n*-pentane gave colorless crystals of 4,5-*exo*-trimethylene-2-*endo*-norbornyl *p*-toluenesulfonate (16,  $\text{R} = \text{Ts}$ ), mp  $50\text{--}51.5^\circ$ ;  $\lambda_{\text{max}}^{\text{OH, 0.01 M NaOH}}$  262.4  $\mu$  ( $\epsilon$  544), 267.6  $\mu$  ( $\epsilon$  492), and 273.4  $\mu$  ( $\epsilon$  438). The infrared and nmr spectra<sup>22</sup> were consistent with the assigned structure.

*Anal.* Calcd for  $\text{C}_{17}\text{H}_{20}\text{O}_4\text{S}$ : C, 66.61; H, 7.24; S, 10.47. Found: C, 66.89; H, 7.14; S, 10.55.

Tricyclic *exo* Acetate 11,  $\text{R} = \text{CH}_3\text{CO}$ . To a solution of *exo* alcohol 11,  $\text{R} = \text{H}$  (50.6 mg, 0.333 mmole), in dry, distilled pyridine (0.55 ml) cooled in an ice bath was added acetic anhydride (0.27 ml). After standing at room temperature for 74 hr, the solution was poured into water and twice extracted with *n*-pentane. The pentane extracts were washed with aqueous copper sulfate solution, water, aqueous sodium bicarbonate solution, and water, dried ( $\text{MgSO}_4$ ), and concentrated, giving 61.0 mg (94%) of 4,5-*exo*-trimethylene-2-*exo*-norbornyl acetate (11,  $\text{R} = \text{CH}_3\text{CO}$ ). The infrared spectrum<sup>22</sup> showed carbonyl absorption at  $5.73\ \mu$  due to acetate; the nmr spectrum showed a doublet of doublets (1 H) due to  $>\text{CHO}$  at 4.70 ppm, a sharp acetyl singlet (3 H) at 2.02 ppm, a broad singlet at 2.23 ppm (1 H) due to the bridgehead proton at  $\text{C}_1$ , and additional peaks upfield.

*Anal.* Calcd for  $\text{C}_{11}\text{H}_{16}\text{O}_3$ : C, 74.19; H, 9.34. Found: C, 74.42; H, 9.59.

Tricyclic *endo* Acetate 16,  $\text{R} = \text{CH}_3\text{CO}$ . The *endo* alcohol 16,  $\text{R} = \text{H}$  (155.5 mg, 1.023 mmoles), was acetylated as described above, giving 190.9 mg (96%) of 4,5-*exo*-trimethylene 2-*endo*-acetate 16,  $\text{R} = \text{CH}_3\text{CO}$ ; the infrared (neat) spectrum showed an ester carbonyl at  $5.73\ \mu$ ; the nmr spectrum showed a broad peak (1 H) due to  $>\text{CHO}$  at 4.98 ppm and other peaks upfield including a sharp acetyl signal (3 H, 2.0 ppm). The molecular weight determined mass spectrometrically was 194.1301 (calcd for  $\text{C}_{13}\text{H}_{18}\text{O}_3$ : 194.1306).

*Anal.* Calcd for  $\text{C}_{13}\text{H}_{18}\text{O}_3$ : C, 74.19; H, 9.34. Found: C, 73.74; H, 9.17.

Tricyclic Epoxide 17. A 0.30 *M* solution of monoperoxyphthalic acid<sup>23</sup> in ether (100 ml, 30 mmoles) was added to tricyclic olefin 10 (1.79 g, 13.3 mmoles) cooled in a salt-ice bath. After standing for 62 hr at  $0^\circ$ , the solution was poured into cold 10% aqueous sodium hydroxide solution. The ethereal solution was washed twice with 10% aqueous sodium hydroxide solution and water, dried ( $\text{MgSO}_4$ ), concentrated, and distilled, giving 1.64 g (82%) of tricyclic epoxide 17, bp  $45^\circ$  (0.6 mm).

The nmr spectrum<sup>22</sup> of 17 ( $\text{CCl}_4$ ) showed one proton of the oxirane ring as a sharp doublet at 2.7 and 2.82 ppm and the other as a broadened doublet at 2.92 and 2.99 ppm and a broad singlet due to the bridgehead proton at  $\text{C}_1$  at 2.41 ppm (1 H), as well as other peaks upfield.

*Anal.* Calcd for  $\text{C}_{10}\text{H}_{14}\text{O}$ : C, 79.96; H, 9.39. Found: C, 80.01; H, 9.47.

Reduction of Tricyclic Epoxide 17 with Lithium Aluminum Hydride. A mixture of the tricyclic epoxide 17 (31 mg, 0.20 mmole), powdered lithium aluminum hydride (24 mg, 0.64 mmole), and dry, distilled glyme (1.0 ml) was stirred at reflux for 30 hr. Water was cautiously added, and the mixture was repeatedly extracted with ether. The ethereal extracts were dried ( $\text{MgSO}_4$ ) and concentrated, giving an oil which was analyzed by vpc. The oil was found to be a mixture of 11,  $\text{R} = \text{H}$  (33%), 12,  $\text{R} = \text{H}$  (63%), and 14 (4%).

Reaction of Tricyclic Epoxide 17 with Aluminum Chlorohydride Reagent. A mixture of lithium aluminum hydride (86.6 mg, 2.28

mmoles) and dry ether (2.0 ml) was refluxed for 30 min. cooled lithium aluminum hydride slurry was added to a so of anhydrous aluminum chloride (262 mg, 1.97 mmoles) i ether (2.0 ml) cooled in an ice bath. The mixture was stirred a period of 0.5 hr at room temperature. A solution of tri epoxide 17 (14.7 mg, 0.0988 mmole) in dry ether (0.5 ml) was to the mixed hydride reagent, and the mixture was refluxed. hr. The reaction mixture was hydrolyzed with water and ext with ether. The ethereal extracts were dried ( $\text{MgSO}_4$ ) and concentrated, giving 13.5 mg (90%) of a mixture of alcohols. mixture was found to consist of 11,  $\text{R} = \text{H}$  (24%), and 14 by vpc analysis.

Isolation of Rearranged Alcohol 14. Alcohols 11,  $\text{R} = \text{H}$  14 were separated by preparative vpc using a 12-ft 5% Car 20M column. The alcohol 14 was obtained as colorless cr, mp  $102\text{--}113^\circ$ ; the nmr spectrum ( $\text{CDCl}_3$ ) showed peaks at 0 (multiplet, 14 H), 3.79 (singlet, 1 H), and 3.94 ppm (singlet, in  $\text{CS}_2$  it showed 0.8–2.5 (multiplet, 14 H), 3.83 (singlet, 1 H 4.40 ppm (singlet, 1 H). The molecular weight determined spectrometrically was 152.1198 (calcd for  $\text{C}_{10}\text{H}_{16}\text{O}$ : 152.120). *Anal.* Calcd for  $\text{C}_{10}\text{H}_{16}\text{O}$ : C, 78.90; H, 10.59. Found: 78.56; H, 10.73.

Oxidation of 14. Rearranged alcohol 14 (15.7 mg, 0.103 m was oxidized as described for the oxidation of the *exo* alcohol  $\text{R} = \text{H}$ , to the tricyclic ketone 15, giving 11.7 mg (76%) of ketone, mp  $119\text{--}130^\circ$ ; infrared ( $\text{CCl}_4$ ) absorption due to carbonyl at  $5.63\ \mu$ . The molecular weight determined mass trometrically was 150.1047 (calcd for  $\text{C}_{10}\text{H}_{14}\text{O}$ : 150.1045).

Mercuriation of Tricyclic Olefin 10 to Give 20,  $\text{E} = \text{HgCl}$ ,  $\text{N} =$  To a stirred solution of tricyclic olefin 10 (134 mg, 1.00 mmole) 61.3% perchloric acid (164 mg, 1.00 mmole), water (0.8 ml) acetone (0.8 ml), freshly prepared yellow mercuric oxide (21 1.00 mmole) was added portionwise. After stirring the mixtu 5 hr, the mercuric oxide had completely dissolved. The a was removed by evaporation, and the mixture was added to t tion of sodium chloride (117 mg, 2.00 mmoles) in water (1. The mixture was shaken for a short time and then filtered suction. The solid was washed with a small amount of wat dried under vacuum, giving 382 mg (99%) of a solid. Rec lization from acetone gave colorless crystals of oxymercu  $\text{E} = \text{HgCl}$ ,  $\text{N} = \text{OH}$ , mp  $198^\circ$ ;  $\lambda$  (KBr) 2.82, 2.92, 3.38, 6.83, 6.94, 7.51, 8.18, 9.02, 9.31, and 11.23  $\mu$ ;  $\nu$  ( $\text{CCl}_4$ ) 3596 (OH).

*Anal.* Calcd for  $\text{C}_{10}\text{H}_{14}\text{ClHgO}$ : C, 30.99; H, 3.91; Cl, Hg, 51.81. Found: C, 31.24; H, 3.92; Cl, 9.03; Hg, 51.7.

Reduction of Oxymercurial 20,  $\text{E} = \text{HgCl}$ ,  $\text{N} = \text{OH}$  Sodium Borohydride. To a stirred mixture of the oxyme (350 mg, 0.90 mmole) and 0.1 *N* sodium hydroxide in me (5 ml) cooled in an ice bath was added sodium borohydrid mg, 1.2 mmoles) in portions over a period of 1.25 hr. The m was refluxed for 3 hr, slowly poured into 10% aqueous l chloric acid solution, and extracted five times with methyle ride. The extracts were dried ( $\text{MgSO}_4$ ) and concentrated, 133 mg (98%) of a colorless, volatile solid. Sublimation at t gave colorless crystals of tertiary alcohol 21, mp  $161\text{--}162^\circ$  frared absorption (in  $\text{CCl}_4$ ) due to OH at 2.65 (sharp) an (broad); nmr peaks ( $\text{CCl}_4$ ) between 1.2 and 2.4 ppm (mult only (no peaks downfield).

*Anal.* Calcd for  $\text{C}_{10}\text{H}_{16}\text{O}$ : C, 78.90; H, 10.59. Found: 79.15; H, 10.63.

A solution of tertiary alcohol 21 (69 mg, 0.45 mmole), anhydride (460 mg, 4.5 mmoles), and dry pyridine (360 m mmoles) under nitrogen was maintained at  $78\text{--}80^\circ$  for t The dark brown solution was poured into water and extracte *n*-pentane. The pentane extract was washed twice with 2 *N* sulfate solution and water, dried ( $\text{MgSO}_4$ ), and concentrated, 76 mg (76%) of the acetate of 21; infrared absorption due t bonyl at  $5.73\ \mu$ ; nmr ( $\text{CCl}_4$ ) 1.0–2.4 ppm (multiplet; sin 1.79 ppm) and no peaks downfield.

*Anal.* Calcd for  $\text{C}_{13}\text{H}_{18}\text{O}_3$ : C, 74.19; H, 9.34. Found: 74.34; H, 9.42.

Tricyclic Tosylate 22. To a solution of alcohol 12,  $\text{R}$  (12.5 mg, 0.0822 mmole), in dry, distilled tetrahydrofuran ml) under nitrogen and cooled in an ice bath was added a *n*-butyllithium solution (0.06 ml, 0.096 mmole) in hexane. solution was stirred at  $0^\circ$  for a period of 30 min. A solut *p*-toluenesulfonyl chloride (19.3 mg, 0.10 mmole) in dry, d tetrahydrofuran (0.25 ml) was added. The solution was for 5.7 hr at  $0^\circ$  and then poured into water. The mixtu extracted with ether, and the extracts were washed with water

us sodium bicarbonate solution and brine, dried ( $\text{MgSO}_4$ ), concentrated, giving 25.3 mg (100%) of tosylate 22;  $\lambda$  (neat) 5.24, 7.22, 8.46, and 12.27  $\mu$ .

**Hydrolysis of Tricyclic Tosylate 22.** A mixture of tricyclic 22 (25.3 mg, 0.0827 mmole), 75% aqueous acetone (1 ml), excess calcium carbonate was stirred at room temperature for a 1 of 20 hr. The reaction mixture was poured into water and tedly extracted with ether. The ethereal extracts were washed water, dried, and concentrated, giving 11.9 mg (95%) of essence rearranged tertiary alcohol 21. The product, as purified reparative vpc, exhibited identical infrared absorption as the ct obtained as described above from 20,  $E = \text{HgCl}$ ,  $N = \text{OH}$ . lcohols prepared by the two methods had the same melting and the melting point of mixtures was undepressed. Both ols showed identical behavior on tlc on silica gel and vpc on t 5% Carbowax 20M column.

**Reaction of Tricyclic Olefin 10.** To a solution of tricyclic 10 (134 mg, 1.00 mmole) in methylene chloride (0.5 ml) d in a salt-ice bath was added a solution of bromine (160 mg, mmole) in methylene chloride (0.5 ml) dropwise with stirring. color of the reagent was immediately discharged with each drop l to the olefin solution. After completion of the addition of romine, the solution was concentrated, giving 280 mg (97%) mixture consisting of a monobromide and mainly dibromide;  $\lambda$  3.38, 6.81, 6.95, 7.70, 7.96, 9.03, 12.61, and 13.61  $\mu$ ; nmr ) 1.0–2.6 (multiplet, 19 H) and 4.07 ppm (singlet, 3 H). mixture gave an immediate precipitate on exposure to alcoholic nitrate.

**Reaction of Bromohydrin 20,  $E = \text{Br}$ ,  $N = \text{OH}$ .** A mixture of y prepared silver oxide (200 mg, 0.87 mmole), crude dibromide mg, 0.38 mmole), and water (2 ml) was refluxed for 17 hr. mixture was filtered, diluted with water, and extracted with

The ethereal extract was dried ( $\text{MgSO}_4$ ) and concentrated, g 50 mg (57%) of a mixture which consisted mainly of bromo ol 20,  $N = \text{OH}$ ,  $E = \text{Br}$ :  $\lambda$  (neat) 2.79, 2.90, 3.40, 5.89, 6.94, 7.32, and 9.01  $\mu$ .

is mixture gave a positive Beilstein test but did not give a itate on boiling for several minutes with a solution of silver e in alcohol.

**Reaction of Bromo Alcohol 20,  $N = \text{OH}$ ,  $E = \text{Br}$ .** To a solution ide bromo alcohol (36 mg, 0.16 mmole) in dry, distilled tetra- furan (1.0 ml) under nitrogen was added di-*n*-butyltin di- de (0.2 ml, 1.0 mmole) by means of a syringe. The solution radiated with light from a sun lamp for 5 min and allowed nd at room temperature for 19 hr. 2-Bromopropane (0.1 ml) added, and the solution was stirred for 1 hr. A 20% aqueous on of sodium potassium tartrate (4 ml) and *n*-pentane was l, the mixture was stirred for 3 hr and filtered through Celite, he pentane layer was separated. The pentane solution was ed with aqueous sodium potassium tartrate solution and water, ( $\text{MgSO}_4$ ), and concentrated, giving 24 mg (99%) of a mixture o compounds. The major product was isolated by preparative 12 mg was collected) and shown to have identical behavior on id vpc with tertiary alcohol 21 prepared by reduction of oxy- rial 20,  $E = \text{HgCl}$ ,  $N = \text{OH}$ . The two alcohols had identical ed spectra and the same melting point; mixtures of the two ols had undepressed melting point.

**Rearrangement of Tricyclic Epoxide 17 on Silica Gel.** The : tricyclic epoxide 17 (230 mg) was chromatographed over gel (Davison, 20 g) using a long column (10  $\times$  300 mm). ing was eluted by *n*-pentane (200 ml), 20% methylene chloride- tane (100 ml), or 50% methylene chloride-*n*-pentane (100 ml). ylene chloride (300 ml) eluted an oil (30 mg), and ethyl ether 1 first (50 ml) an oil (22 mg) and then (100 ml) a colorless (73 mg). The colorless solid eluted by ethyl ether was the 0,  $E = N = \text{OH}$ , mp 159–161°;  $\lambda$  ( $\text{CH}_2\text{Cl}_2$ ) 2.93 (OH), 3.36, 7.03, 8.32, 8.95, 9.26, 9.53, and 11.03  $\mu$ ; nmr ( $\text{CCl}_4$ ) 1.2–2.2 iplet, 13 H), 3.88 (singlet, 1 H), and 4.64 ppm (singlet, 2 H); ( $\text{CDCl}_3$ ) 1.2–2.2 (multiplet, 13 H), 3.86 (singlet, 2 H), and 3.98 (singlet, 1 H).

*Anal.* Calcd for  $\text{C}_{10}\text{H}_{16}\text{O}_2$ : C, 71.39; H, 9.59. Found: C, ; H, 9.63.

e diol 20,  $E = N = \text{OH}$ , did not react with periodic acid.

**Acid-Catalyzed Hydrolysis of Tricyclic Epoxide 17.** A stirring e of tricyclic epoxide 17 (150.3 mg, 1.00 mmole), water (0.6 and 72% perchloric acid (1 drop) was maintained at 60° for a d of 1 hr. The mixture was neutralized with 0.1 *N* sodium xide, diluted with water, and extracted three times with . The ethereal extracts were dried ( $\text{MgSO}_4$ ) and concentrated; lid residue was sublimed twice and recrystallized twice from

*n*-hexane, giving 22 mg (13%) of diol 20,  $E = N = \text{OH}$ , mp 148–150°, having the same infrared spectrum as the product from the previous procedure.

**Hydroxy Ketone 23.** Diol 20 (18.6 mg, 0.111 mmole) was oxi- dized as described for the oxidation of 11,  $R = \text{H}$ , to tricyclic ke- tone 15, giving 9.1 mg (50%) of hydroxy ketone 23, infrared absorp- tion ( $\text{CCl}_4$ ) 5.64  $\mu$ . The molecular weight determined mass spec- trometrically was 166.0992 (calcd for  $\text{C}_{10}\text{H}_{14}\text{O}_3$ : 166.0994).

**Lactone 24.** Anhydrous sodium acetate (102 mg) was added to peracetic acid ("Becco 40%," 10 g), and this solution (5 ml) was diluted with methylene chloride (10 ml). The methylene chloride solution was filtered through cotton and titrated (4.50 *N*). To the tricyclic ketone 15 (115 mg, 0.769 mmole) was added buffered peracetic acid in methylene chloride (2.0 ml, 9.0 mequiv). After allowing the reaction mixture to stand for 85 hr at 26–28°, additional peracetic acid solution (1.0 ml, 4.5 mequiv) was added, and the reaction mixture was allowed to stand for another 96 hr at 26–28°. The mixture was poured into water and extracted three times with ether. The ethereal extracts were washed with sodium bicarbonate solution, sodium bisulfite solution, and water, dried ( $\text{MgSO}_4$ ), con- centrated, and distilled, giving 102 mg (80%) of lactone 24; infrared absorption ( $\text{CCl}_4$ ) due to carbonyl at 5.71  $\mu$ , no OH absorption; nmr spectrum ( $\text{CS}_2$ ): peak at 4.72 ppm (apparent quintet, 1 H) due to  $>\text{CHOCO}$  and other peaks upfield between 1.0 and 2.9 ppm.<sup>22</sup>

*Anal.* Calcd for  $\text{C}_{10}\text{H}_{14}\text{O}_3$ : C, 72.26; H, 8.49. Found: C, 72.55; H, 8.54.

**Hydrolysis and Oxidation of 24.** A solution of lactone 24 (645 mg, 3.88 mmoles) and potassium hydroxide (5.67 g, 0.101 mole) in methanol (180 ml) was refluxed for 13 hr. Evaporation of most of the methanol, dilution with water, ether extraction (discarded), dropwise addition of 2 *N* sulfuric acid (99 ml, 0.198 mole) at 0°, and extraction with ether gave 688 mg (96%) of hydroxy acid, mp 90–98°, which was methylated with ethereal diazomethane (3 hr), giving 685 mg (91%) of hydroxy ester which then was oxidized by chromic acid to give 562 mg (83%) of keto ester 25,  $R = \text{CH}_3$ . This ester showed carbonyl absorption due to ketone and ester functions at 5.74  $\mu$  (in  $\text{CCl}_4$ ), indicating that the ketone function was present in a five-membered ring. A considerable number of further transformations of this substance are given in the thesis cited in ref 22.

**Transformation of the Epoxide 17 to the Tetracyclic Alcohol 18.** To a stirred solution of dry, distilled diethylamine (445 mg, 6.01 mmoles) in sodium-dried benzene (2.8 ml) under nitrogen and cooled in an ice bath was added a 1.6 *M* solution of *n*-butyllithium in hex- ane (2.8 ml, 4.48 mmoles) by means of a syringe. The mixture was stirred for 20 min. A solution of tricyclic epoxide 17 (399 mg, 2.66 mmoles) in sodium-dried benzene (2.8 ml) was added to the lithium diethylamide mixture. The reaction mixture was stirred and refluxed for a period of 48 hr. The mixture was cooled, poured into ice-water, and extracted twice with ether. The combined ethereal extracts were washed with saturated aqueous ammonium chloride solution and water, dried ( $\text{MgSO}_4$ ), concentrated, and dis- tilled [50–60° (0.4 mm)], giving 342 mg (86%) of tetracyclic alcohol 18, mp 56–70°; near-infrared ( $\text{CCl}_4$ ) absorption at 1.676  $\mu$  ( $\epsilon$  0.38); nmr ( $\text{CCl}_4$ ) 1.0–2.1 (multiplet, 14 H), 3.86 (singlet, 1 H), and 4.45 ppm (singlet, 1 H). The molecular weight determined mass spectrometrically was 150.

*Anal.* Calcd for  $\text{C}_{10}\text{H}_{14}\text{O}$ : C, 79.96; H, 9.39. Found: C, 79.96; H, 9.32.

The tetracyclic alcohol 18 (50.3 mg, 0.335 mmole) was acetylated using acetic anhydride-pyridine giving 63.4 mg (98%) of the corre- sponding acetate, infrared absorption at 5.73  $\mu$ ; nmr ( $\text{CDCl}_3$ ) 1.1–2.2 (multiplet, 15 H) and 4.72 ppm (multiplet, 1 H). The molecular weight determined mass spectrometrically was 192.1138 (calcd for  $\text{C}_{12}\text{H}_{18}\text{O}_2$ : 192.1150).

*Anal.* Calcd for  $\text{C}_{12}\text{H}_{18}\text{O}_2$ : C, 74.97; H, 8.39. Found: C, 74.81; H, 8.42.

From the tetracyclic alcohol 18 (30.4 mg, 0.203 mmole) a tosylate was prepared using *p*-toluenesulfonyl chloride (38.1 mg, 0.200 mmole in sodium-dried ether (0.5 ml) and powdered potassium hydroxide (30.2 mg, 0.539 mmole) added portionwise at  $-10^\circ$ . The mixture was stirred at 0–5° for a period of 12 hr, poured into water, and extracted with ether. The ethereal extract was dried ( $\text{MgSO}_4$ ) and concentrated, giving 54.0 mg (88%) of a colorless solid. Two recrystallizations from *n*-pentane gave colorless crystals of tosylate 18, mp 66.5–69°;  $\lambda_{\text{max}}^{\text{AOR, 0.01M N}_2\text{O}_4}$  262.0  $m\mu$  ( $\epsilon$  486), 267.4  $m\mu$  ( $\epsilon$  423), and 273.0  $m\mu$  ( $\epsilon$  350). The molecular weight determined mass spectrometrically was 304.1137 (calcd for  $\text{C}_{17}\text{H}_{20}\text{O}_3\text{S}$ : 304.1133).

**Reaction of *p*-Toluenesulfonate of 18 with Sodium Borohydride in Aqueous Diglyme.** A solution of the *p*-toluenesulfonate of 18 (88.8 mg, 0.292 mmole), sodium borohydride (94.7 mg, 2.51 mmole), and sodium hydroxide (24.5 mg, 0.613 mmole) in 65 vol. % aqueous diglyme (0.6 ml) was stirred for 16 hr at room temperature. The solution was poured into water and extracted twice with trichlorofluoromethane (Freon 11). The extracts were washed with water, dried (MgSO<sub>4</sub>), and concentrated, giving a mixture of products. The mixture was analyzed by vpc and found to consist of tetracyclic alcohol 18 (75%) and a 9:1 mixture of hydrocarbons (25%). The minor hydrocarbon had the same retention time on a 200-ft tricyanoethoxypropene capillary (0.011 in.) column as tricyclic olefin 10, and the major hydrocarbon was 1,2-trimethylenenorbornene, which was obtained pure by preparative vpc; nmr (CS<sub>2</sub>) 0.9–2.2 ppm (multiplet). The molecular weight determined spectrometrically was 134.1094 (calcd for C<sub>10</sub>H<sub>14</sub>: 134.1095).

**4,5-Trimethylenenorbornene (26).** The alcohol 18 (197 mg) was oxidized as described for the oxidation of 11, R = H, to 15, giving 132 mg (70%) of tetracyclic ketone 26,  $\lambda_{\text{max}}^{\text{KIOH}}$  271 m $\mu$  ( $\epsilon$  46); infrared (CCl<sub>4</sub>)<sup>22</sup> carbonyl absorption 5.67 and 5.72  $\mu$ ; nmr (CCl<sub>4</sub>) 1.2–2.2 ppm (multiplet). The molecular weight determined mass spectrometrically was 148.

*Anal.* Calcd for C<sub>10</sub>H<sub>12</sub>O: C, 81.04; H, 8.16. Found: C, 81.34; H, 8.23.

Tetracyclic ketone 26 was not reduced by zinc in acetic acid at reflux nor by hydrogen and 10% palladium on charcoal in acetic acid at room temperature at 1 atm.

**5-Bromo-4,5-trimethylenenorbornanone (27) and Its Reduction.** A 0.36 M solution of anhydrous hydrobromic acid (38 ml, 13.7 mmole) in methylene chloride was added to tetracyclic ketone 26 (1.19 g, 8.04 mmole). After standing at room temperature for a period of 17 hr, the solution was concentrated, giving 1.65 g (90%) of a brown semisolid. Sublimation gave colorless crystals of bromo ketone 27, mp 146–148°; infrared absorption (CCl<sub>4</sub>) 5.70  $\mu$ ; nmr (CCl<sub>4</sub>) 1.5–2.7 ppm (multiplet). The mass spectrum showed two peaks of equal intensity at 228 and 230.

Reduction of 27 with the following reagents gave tricyclic ketone 15: zinc in acetic acid, di-*n*-butyltin dihydride in tetrahydrofuran, and hydrogen and 10% palladium on charcoal in 95% ethanol. The products were analyzed by infrared absorption and vpc with a 12-ft 5% Carbowax 20M column.

**Acetolysis Products from 4,5-*exo*-Trimethylene-2-*exo*-norbornyl *p*-Toluenesulfonate (11, R = Ts).** A solution of the *exo-p*-toluenesulfonate 11, R = Ts (102.3 mg, 0.334 mmole), in 0.010 M sodium acetate in anhydrous acetic acid solution (60 ml) was stirred and maintained at 81–83° for 5 hr (*ca.* ten half-lives). The cooled solution was diluted with water, neutralized with sodium carbonate, and repeatedly extracted with ether. The combined ether extracts were washed with water, saturated aqueous sodium bicarbonate solution, and water, dried (MgSO<sub>4</sub>), concentrated, analyzed by vpc, and distilled, giving 55.4 mg (85%) of tricyclic *exo* acetate 11, R = CH<sub>3</sub>CO. This product had the same vpc retention time, the same infrared spectrum, and the same nmr spectrum as the *exo*

acetate 11, R = CH<sub>3</sub>CO, prepared by acetylation of 11, R = H. A considerable study was made of various columns for vpc analysis of mixtures of 11, R = H, and 16, R = H, and also of mixture of the corresponding acetates; this analysis was not possible using long 0.25- or 0.125-in. columns with a large variety of stationary phases (both polar and nonpolar), since the chromatographic behavior of the *exo*, *endo* isomers was essentially identical. Slight separation was noted using tricyanoethoxypropene as stationary phase with the acetates 11, R = CH<sub>3</sub>CO, and 16, R = CH<sub>3</sub>CO, and it proved possible to achieve acceptable resolution using this stationary phase in a 200-ft, 0.11 in. capillary column at 100°. The total mixture obtained from the above experiment before distillation was analyzed in this way. Peaks were observed at the following retention times (min): 5.3 (3.5%), 5.5 (sh, *ca.* 1%), 37–39.5 (4%, broad, includes two or more unresolved), 41.3 (91.5%, corresponds to 11, R = CH<sub>3</sub>CO, the major product). It seems likely, though by no means certain, that the broad peak at 37–39 min contains the *endo* acetate 16, R = CH<sub>3</sub>CO, as a component, since the latter exhibits a peak at 39 min under the conditions of this analysis. The tricyclic olefin 10 under these conditions exhibits a retention time of 5.3 min.

**Acetolysis of 4,5-*exo*-Trimethylene-2-*endo*-norbornyl *p*-Toluenesulfonate (16, R = Ts).** A solution of the *p*-toluenesulfonate 16, R = Ts (99.0 mg, 0.324 mmole), in 0.010 M sodium acetate in anhydrous acetic acid solution (60 ml) was stirred and maintained at 100–103° for 5 hr (*ca.* ten half-lives). After neutralization and ether work-up, the product was analyzed by vpc and distilled, giving 55.2 mg (88%) of tricyclic *exo* acetate 11, R = CH<sub>3</sub>CO. This product had the same retention time on vpc, the same infrared spectrum, and the same nmr spectrum as prepared by acetylation of 11, R = H. The vpc analysis of the total product before distillation was performed on the 200-ft capillary tricyanoethoxypropene column at 100° under the same conditions as used for the previously described analysis. The vpc product analysis, which was very similar to that for the acetolysis of 11, R = Ts, revealed components at the following retention times (min): 5.3 (2.5%), 5.5 (1.5%), 37–39.5 (4%, broad), and 42.2 (92%), the last of which corresponds to 11, R = CH<sub>3</sub>CO.

**Kinetic Data.** The method of Swain and Morgan<sup>23</sup> was used with a Cary Model 14 spectrophotometer equipped with a thermostated cell compartment. Acetolyses were conducted in quartz cells sealed with tightly fitting Teflon stoppers. The *p*-toluenesulfonate was dissolved in *ca.* 10 ml of anhydrous acetic acid (dried with molecular sieves and distilled) containing fused sodium acetate at a concentration of 0.01 M. Excellent first-order rate constants were obtained (for tables of original data see thesis cited in ref 22). Measurements of the rate constants for acetolysis of *exo*- and *endo*-norbornyl *p*-toluenesulfonates gave results in excellent agreement with values previously obtained by titrimetric analysis.<sup>27</sup>

# Syntheses and Reactions of 3-Substituted Tricyclo[3.3.0.0<sup>2,6</sup>]octanes and of Tricyclo[3.3.0.0<sup>2,6</sup>]oct-3-ene<sup>1</sup>

Jerrold Meinwald and Bruce Emil Kaplan

Contribution from the Department of Chemistry, Cornell University, Ithaca, New York 14850. Received December 8, 1966

**Abstract:** Photochlorination of tricyclo[3.3.0.0<sup>2,6</sup>]octane (2) leads to 3-chlorotricyclo[3.3.0.0<sup>2,6</sup>]octane (9), resulting from preferential attack at the secondary positions. Similarly, chromyl acetate oxidation of 2 gives tricyclo[3.3.0.0<sup>2,6</sup>]octan-3-one (10) as the chief product, accompanied by a smaller amount of tricyclo[3.3.0.0<sup>2,6</sup>]oct-3-yl acetate (11). The acetolysis of the corresponding tosylate (13) was found to proceed at a rate about 180 times that of bicyclo[2.1.1]hex-2-yl tosylate (18), producing a mixture of unrearranged and rearranged products (11, 14, and 15). These observations are accommodated by consideration of the difference in degree of substitution and in geometry between the tricyclic and bicyclic esters. Finally, tricyclo[3.3.0.0<sup>2,6</sup>]oct-3-ene (4) was obtained *via* tricyclo[3.3.0.0<sup>2,6</sup>]oct-3-ylamine (30) using a Hofmann elimination sequence. Some unexpected features of the nmr and ultraviolet spectra of this strained olefin are described.

63 Srinivasan reported that the gas-phase, mercury-sensitized photoisomerization of *cis,cis*-cyclooctadiene (1) gives tricyclo[3.3.0.0<sup>2,6</sup>]octane % yield.<sup>2</sup> Shortly thereafter,<sup>3,4</sup> he was able to use a solution photolysis technique which gave a yield of 2. These developments, along with our continuing interest in the highly strained bicyclo[2.1.1]-ring system (3), prompted an investigation of the

is and reactions of functionalized tricyclo[3.3.0.0<sup>2,6</sup>]octanes. Some of our specific goals were production of substituents at C<sub>3</sub> of 2, to permit mass ion studies analogous to those already carried out on bicyclo[2.1.1]hexanes.<sup>5-9</sup> Another objective was to use such functionalized derivatives as intermediates for a synthesis of tricyclo[3.3.0.0<sup>2,6</sup>]oct-3-ene analogous to the as yet unknown bicyclo[2.1.1]-

ene. We wish now to present our results in these

ion

to obtain tricyclo[3.3.0.0<sup>2,6</sup>]octane for extensive study the irradiation of 1,5-cyclooctadiene was carried out under conditions slightly different from those previously described.<sup>2</sup> By increasing the concentration of cyclooctadiene about fourfold and by allowing the

partial support of this research by the National Institutes of Health (10090) is acknowledged with pleasure.

conversion to proceed almost to completion, yields of ca. 50% and absolute amounts of 15–50 g of 2 could be realized in a single experiment.

Srinivasan found in this initial study that 2 was not the only product of the irradiation of 1,5-cyclooctadiene in solution. Thus, when the reaction was carried out in ether with cuprous chloride or rhodium chloride as catalyst, four products were identified: the tricyclo[3.3.0.0<sup>2,6</sup>]octane 2, 1,3-cyclooctadiene (5), 1,4-cyclooctadiene (6), and bicyclo[4.2.0]octene-7 (7).

We have found that one previously undetected product consistently comprised about 10% of the reaction mixture. An elemental analysis indicated that this component was another C<sub>8</sub>H<sub>12</sub> isomer. Its nmr spectrum showed no absorption in the olefinic region, but upfield absorption attributable to a cyclopropane grouping was apparent. A comparison of the nmr and infrared spectra of this compound with those of an authentic sample of *cis,anti,cis*-tricyclo[3.3.0.0<sup>2,6</sup>]octane (8) showed two compounds to be identical.<sup>10,11</sup> Although the formation of 8 might be rationalized by a small variation of the free radical chain mechanism proposed recently to account for the formation of 2 from 1,<sup>12a</sup> it now appears more correct to view this

as an independent side reaction rather than as one based upon a common intermediate.<sup>12b</sup>

With 2 readily available we examined methods to functionalize the hydrocarbon skeleton. Since free radical reactions generally occur without structural rearrangement, even in highly strained systems, this was the first type of reaction to be tried. Two free

radical substitutions which proved useful were chlorination and chromyl acetate oxidation.

In the chlorination of acyclic hydrocarbons it has been found that the order of reactivity of aliphatic carbon-hydrogen bonds toward chlorine is tertiary > secondary > primary.<sup>13</sup> In alicyclic compounds, however, this order is not necessarily the same. Thus, in the chlorination of bicyclo[2.2.1]heptane only two products have been isolated, both of which involve attack at the C<sub>2</sub> position.<sup>14</sup> The liquid-phase photochlorination of **2** led to analogous results; the only product detected, isolable in 50% yield, was 3-chlorotricyclooctane (**9**). The glpc of this product on several analytical columns indicated the presence of only one component. Its

elemental analysis was compatible with the molecular formula C<sub>8</sub>H<sub>11</sub>Cl. The nmr spectrum showed a complex doublet centered at  $\tau$  5.46 (1 proton, assignable to that at C<sub>3</sub>), and a complex series of peaks, subsequently found to be characteristic of 3-substituted derivatives of **2**, from  $\tau$  7.3 to 8.2 (10 protons).

The liquid-phase bromination of **2** was also carried out, but was unexpectedly complex. The reaction may have followed a carbonium ion pathway rather than a free radical pathway. (An example of a hydrocarbon bromination which apparently utilizes a carbonium ion mechanism is provided by the conversion of adamantane to 1-bromoadamantane.<sup>15</sup>) The product, which appeared to contain two bromine atoms, was not fully characterized.

The oxidation of hydrocarbons by chromic acid, chromyl acetate, or chromyl chloride is also reported to be a free radical substitution reaction.<sup>16</sup> The relative rates of attack on aliphatic carbon-hydrogen bonds are typical of rates of free radical reactions, that is, tertiary > secondary > primary.<sup>17</sup> The alcohols formed initially in these reactions are often further oxidized to ketones. This technique provides a useful ketone synthesis when the product is not readily degraded by enolization and subsequent oxidation.<sup>8, 18, 19</sup>

Chromyl acetate oxidation of **2** gave tricyclo[3.3.0.0<sup>2,6</sup>]octan-3-one (**10**) and tricyclo[3.3.0.0<sup>2,6</sup>]oct-3-yl acetate (**11**), characterized as described below. They were formed in a ratio of 9:1, as determined by glpc, in an over-all yield of ca. 60% based on the tri-

cyclooctane consumed. The structure of **10** follows from its elemental analysis, from its mass spectrum, which showed a parent peak at  $m/e$  122, from its infrared absorption maximum at 5.68  $\mu$  (carbonyl stretching), and from a series of reactions, described later, which relate ketone **10** to **2**. The acetate **11** could be separated from the crude ketone by a zone freezing technique, and was shown to be identical with authentic **11**, prepared, as described below, from alcohol **12**.

The nmr spectrum of **10** is simplified by a coincidence of chemical shift values. While there are six different types of carbon-hydrogen bonds in the molecule, the spectrum shows only four sharp bands at  $\tau$  7.40 (2), 7.78 (2), 7.86 (2), and 8.13 (4). This pattern of absorption can be explained by assuming that all four hydrogens at C<sub>7</sub> and C<sub>8</sub> (a and b, formula **10a**) have the same chemical shift, and that those at C<sub>2</sub> and C<sub>1</sub> (f and d) are also equivalent.

Reduction of **10** with lithium aluminum hydride gave the alcohol **12** in 80% yield. The corresponding tosylate **13** was prepared in 90% yield by the treatment of **12** with *p*-toluenesulfonyl chloride in pyridine. The elemental analyses of **12** and **13** and their infrared and nmr spectra were consistent with the assigned structures.

The rate of acetolysis of **13** was determined titrimetrically, at 35.0 and 50.0°, by standard methods.<sup>20, 21</sup> Excellent first-order kinetics were observed over several half-lives. Three products were characterized from this acetolysis. The first (20%) was identified as bicyclo[3.3.0]octa-2,6-diene (**14**) by comparison with an authentic sample.<sup>22</sup> Unrearranged acetate **11** was formed in 40% yield, and the ring-opened acetate **15** in 17% yield. The acetates were reduced with lithium

aluminum hydride, and the resulting alcohols were separated by preparative glpc. The alcohol from the reduction of **11** was identical in every respect with the previously characterized tricyclic alcohol **12**. The alcohol from the reduction of acetate **15** was hydrogenated over Adam's catalyst. A phenylurethan of this alcohol had the same melting point as that reported for the phenylurethan of **16**.<sup>23</sup> The hydrogenated alcohol was oxidized with N-bromosuccinimide, following a procedure

of Cope,<sup>23</sup> to give a ketone, the 2,4-dinitrophenylhydrazone of which had the same (broad) melting point as that of the known derivative of ketone 17.<sup>24</sup> Thus

the *cis* fusion of the rings and the position of the oxygen is certain, as is the *exo* configuration of the alcohol, although a small amount of the *endo* alcohol might have gone unobserved. The position of the double bond of 15 is assigned on mechanistic grounds and on the basis of the great similarity of the nmr spectra of 14 and 15 in the olefinic proton region.

To rationalize both the rate of solvolysis of 13 and the products formed, we may compare these results with those obtained for carbonium reactions at C<sub>2</sub> in the bicyclo[2.1.1]hexane series. The relative rates for the acetolysis of bicyclo[2.1.1]hexyl 2-tosylate (18), 5,5-dimethylbicyclo[2.1.1]hexyl 2 $\alpha$ -tosylate (19), and

tosylate 13 (extrapolated to 75°) are 1:36:180.<sup>5,25</sup> A major factor influencing the rate of ionization is the internal angle at the carbon atom where the ionization occurs.<sup>26-28</sup> Although knowledge of the pertinent molecular geometry from direct physical measurement is often lacking, estimates are available from a correlation of carbonyl stretching frequencies with included angle.<sup>28</sup> The carbonyl stretching band of both 20 and 21 is found at 1764 cm<sup>-1</sup>, while that of 13 is at 1758 cm<sup>-1</sup>. These frequencies lead to calculated angles of 95.5° for 20 and 21, and 98.5° for 10. If the internal

angles were the only determining factor in the rates of acetolysis, then one would expect 18 and 19 to have the same solvolysis rate, and 13 to have a rate *ca.* 15 times faster. A possible explanation for the difference in rate between 18 and 19 may be found in the hypothesis that these esters yield bridged, delocalized ions in which positive charge is distributed over three positions.<sup>5,25</sup> The bridged carbonium ion 22, derived from 18, would spread its charge to a primary carbon in one of its contributing forms, whereas the bridged carbonium ion 23, derived from 19, has two additional methyl groups providing a tertiary site in place of the primary site in 22 to help stabilize the positive charge. If a similar type of bridged ion were formed in the solvolysis of 13, a reasonable model for comparison would be the presently unknown ester 24, with one methyl substituent to aid the leaving of the tosylate group. In both the

hypothetical bridged carbonium ion which would be formed from 24 and that expected from 13, the electron deficiency would be shared by a secondary carbon. To predict the rate of acetolysis of 24 relative to the rate of 18 and 19, we will simply choose the average of that for 18 and 19, which is 18. This would make the relative rates of 24:13 18:180, or 1:10. Correcting for the difference in angle at C<sub>2</sub> of the bicyclo[2.1.1]hexane nucleus and C<sub>3</sub> of the tricyclo[3.3.0.0<sup>2,6</sup>]octane nucleus,<sup>26,28</sup> the expected relative rates for the hypothetical model and 13 become 1.4:1. On the basis of these crude estimates, the acetolysis rate of 13 agrees well with expectations.

It should be noted that this type of argument, which appears plausible for the cases just discussed, cannot be applied successfully to the bicyclo[2.2.1]heptyl analogs of 18 and 19, 18a and 19a.<sup>29</sup> Thus, in the

bicyclo[2.2.1]heptyl series, Schleyer, *et al.*, found that 6,6-dimethyl-2-*exo*-bicyclo[2.2.1]heptyl tosylate (19a) was *less* reactive than 2-*exo*-bicyclo[2.2.1]heptyl tosylate (18a) by a factor of *ca.* 14 at 75°. These results are contrary to those which might have been expected if a bridged ion (23a) with significant contribution from the resonance form with positive charge on the tertiary site (C<sub>6</sub>) were produced. Schleyer, *et al.*,<sup>29</sup> have rationalized the deactivation of 19a by assuming that the *endo*-6-methyl substituent suffers unfavorable steric interactions in going to a bridged transition state (23a). Since the geometric situation is quite different in 19 and 23, however, this steric effect may well not be felt. In fact, the C<sub>1</sub>-C<sub>6</sub> bond loosening implied in structure 23, which corresponds to partial opening of a cyclobutane ring, with concomitant strain relief, could be a factor operating in the opposite direction, encouraging contribution from the resonance form with positive charge at C<sub>5</sub> in the bicyclo[2.1.1]hexyl series.

The acetolysis product obtained from 18, after reduction with lithium aluminum hydride, is bicyclo[2.1.1]hexan-2-ol (26), whereas the product of the acetolysis of 19, after reduction, is the ring-opened tertiary alcohol, 27. The formation of 26 and 27 is consistent with the bridged carbonium ion hypothesis. Acetic acid could be expected to attack ions 22 and 23 at the positions of greatest positive charge density.<sup>30</sup> Attacked in this way, 22 would yield the acetate of 26. In the case of 23, bonding of a solvent molecule to the position of greatest positive charge density (tertiary) would give the acetate of 27. Similarly, ion 28 formed from the solvolysis of 13 has no obvious position of "greatest" charge density, since all relevant positions are secondary.

(30) J. A. Berson, *Tetrahedron Letters*, **16**, 17 (1960).

On this basis, solvent attack at both C<sub>2</sub> and C<sub>6</sub> with concomitant ring opening appears reasonable.

Another very significant experimental difference between the bicyclo[2.2.1]heptyl and bicyclo[2.1.1]hexyl series is that 19a suffers acetolysis, giving exclusively the *unrearranged* 6,6-dimethyl-2-*exo*-bicyclo[2.2.1]heptyl acetate,<sup>33</sup> while 19 yields *ring-opened* acetate as at least 98% of the acetate produced.<sup>25</sup> Thus, the *differences* between the effects of *gem*-dimethyl substitution in 19 and 19a are apparent from both the kinetic results and the products obtained.

The introduction of a double bond into the tricyclo[3.3.0.0<sup>2,6</sup>]octane nucleus was another objective of this study. One of the reasons for our interest in this olefin is that all attempts to synthesize the closely related bicyclo[2.1.1]hexenes have as yet been unsuccessful.<sup>31</sup> A series of reactions which led to the successful preparation of 4 are described below.

Ketone 10 reacted with hydroxylamine to give oxime 29 in 95% yield. This oxime was reduced with lithium aluminum hydride in tetrahydrofuran to give amine 30 in 80% yield. (It has been shown that adamantylamine hydrochloride (31) has both *in vitro* and *in vivo* antiviral activity.<sup>32</sup> It will be of interest to see whether the somewhat related hydrochloride of 30 is associated with similar biological activity.)

Amine 30 was converted to the dimethylamine 32 in 80% yield by the Eschweiler-Clarke technique.<sup>33</sup> Methyl iodide in ether converted 32 to the trimethylammonium iodide 33a, which was then treated with a suspension of silver oxide to form the trimethylammonium hydroxide 33b. This product decomposed in a nitrogen atmosphere at *ca.* 100° (12 mm) to give 4 in 29% yield, accompanied by 53% of recovered 32.

(The formation of 32 corresponds to a common side reaction in many Hofmann elimination reactions.<sup>34</sup>) In an attempt to obtain better yields of 4, the amine oxide 34 was prepared from 32 and 30% hydrogen per-

oxide. Disappointingly, the decomposition of 32 required unusually high temperatures (180–210°), and gave as its main product not 4, but an unidentified product which seemed to be aromatic. This study of 34 was not carried further.

The olefinic product obtained from 33b had the expected elemental analysis, and its molecular formula was confirmed by its mass spectrum, which showed a parent peak at *m/e* 106. A small sample of 4 was hydrogenated over Adams' catalyst, and the product was found to be identical with the parent tricyclooctane 2, as shown by nmr and infrared spectra, and by glpc comparisons. This reaction proved that the basic tricyclic nucleus had remained unchanged throughout the series of reactions which culminated in the formation of 4.

The nmr spectrum of 4 shows four groups of absorption bands centered at  $\tau$  3.93 (2 protons), 6.53 (2 protons), 8.15 (2 protons), and 8.27 (4 protons). A tentative assignment of these absorption bands, based upon the chemical shifts of closely related absorption bands in bicyclo[2.2.1]heptene,<sup>35</sup> bicyclo[2.2.1]heptadiene,<sup>36</sup> and tricyclooctane, is given below. The spin-spin couplings are described in the Experimental Section. Although the coupling pattern appears to be rationalized, it should be noted that this spin-spin coupling may be

“deceptively simple.”<sup>36</sup> One interesting aspect of the nmr spectrum of 4, assuming the above assignment of the absorption bands, is the long-range coupling ( $J$  = *ca.* 2 cps) between the olefinic ( $\tau$  3.93) and homoallylic ( $\tau$  8.15) protons, d and b. These protons do not have the “W” geometry usually associated with four-bond proton-proton coupling.<sup>37</sup> The alternate explanation that the coupling of the olefinic protons is actually with the adjacent allylic rather than with the homoallylic protons would appear at first to require quite unusual chemical shift assignments, as shown in formula 4a. Interesting precedent for these unexpected assignments, however, is provided by the nmr spectrum

of benzvalene (35), which has recently been synthesized, and which appears to have its allylic proton resonance

ppm upfield from that of the homoallylic proton. The problem of distinguishing between these

possible rationalizations of the nmr spectrum of 4 (table one), and clarification of the assignment of 8.15 and 6.53 bands will have to await further investigation.

The nmr spectrum of 4 affords an opportunity to test the degree of s character in the vinyl carbon-hydrogen bonds on the basis of the corresponding  $H-^{13}C$  coupling constant.<sup>39</sup> The coupling constant  $J_{HC-H}$  is upon the bond order, and varies from  $J = 125$  cps for an  $sp^3$  bond to  $J = 250$  cps for an  $sp$  bond.<sup>39</sup> Carbon-hydrogen spin-spin coupling constants of 4 and of 4, itself are collected in Table I.<sup>40</sup> It would appear from these data that 4 has more s character in its vinyl carbon-hydrogen bonds than does bicyclo[2.2.1]heptene, and less than bicyclo[2.2.1]heptadiene.

Compd	$J_{HC-H}$ , cps	$J_{HC-CH_2}$ , cps
cyclopentene	160.5	5.8
cyclopentadiene	170	...
stylylene	156.8	11.4
bicyclo[2.2.1]heptene	165.5	6.0
bicyclo[2.2.1]heptadiene	172.5	5.2
tricyclo[3.3.0.0 <sup>3,7</sup> ]octene	167 ± 1	5.1

The ultraviolet absorption spectrum of 4 appears of particular interest. Its longest wavelength band is at  $ca. 251 m\mu$ , whereas the comparable absorption is at  $ca. 208 m\mu$  in cyclopentene, at  $ca. 213 m\mu$  in bicyclo[2.2.1]heptene, and at  $ca. 221 m\mu$  in bicyclo[2.2.1]heptadiene.<sup>41,42</sup> This ultraviolet spectrum is receiving more careful examination, and will be discussed elsewhere.<sup>43</sup>

In summary, tricyclooctane 2 has been functionalized and the acetolysis of the corresponding 3-tosyloxy derivative has been studied. In addition, tricyclooctane has been synthesized for the first time. This synthesis, which shows several unexpected spectral properties, provides the first example of a simple bicyclohexene.

## Experimental Section

Boiling points and melting points are uncorrected. Column chromatography was carried out on Woelm neutral alumina.

Microanalyses were performed by the Scandinavian Microanalytical Laboratory, Herlev, Denmark, and by the Galbraith Laboratories, Knoxville, Tenn.

**Gas-Liquid Partition Chromatography (Glpc).** Analytical determinations were carried out on Aerograph Models 600 Hy-F1 and 660 Hy-F1. Columns of the following liquid phases on Firebrick were used: 30% Ucon oil nonpolar; BDS (15% butanediol succinate); 30% Carbowax 20M; TCEP (20% 1,2,3-tris(2-cyanoethoxy)propane).

A Beckman GC-2 gas chromatograph was used for preparative glpc. The following columns were used: Carbowax, 10 ft of 30% Carbowax 20M; TCEP, 12 ft of 20% 1,2,3-tris(2-cyanoethoxy)propane.

**Infrared Spectra.** Most infrared spectra were run on a Perkin-Elmer Infracord Model 137 B. The carbonyl stretching frequencies of ketones 10 and 20 were measured on a Perkin-Elmer Model 521.

**Nuclear Magnetic Resonance Spectra.** Nmr spectra were taken on a Varian A-60 spectrometer, in carbon tetrachloride, unless otherwise noted.

**Mass Spectra.** All mass spectra were run on a CEC 21-103A spectrometer. Each spectrum was calibrated with a compound of known mass.

**Ultraviolet Spectra.** All ultraviolet spectra were taken on a Cary Model 14 spectrophotometer in the specified solvent.

**Tricyclo[3.3.0.0<sup>3,7</sup>]octane (2).**<sup>3</sup> A solution of 1,5-cyclooctadiene (25.3 g, 0.234 mole) and cuprous chloride (0.1 g) in ether (1.8 l.) was irradiated in a 2-l. Vycor flask (equipped with a condenser and drying tube) by a bank of 16 GE 68T5 lamps placed around the flask. After 1 day a green precipitate had formed. The reaction mixture was filtered and the flask washed with nitric acid. The filtrate was returned to the flask and irradiated for an additional 4 days. By the end of this period, a black, finely divided precipitate had formed and coated the walls of the flask. The reaction mixture was again filtered and returned to the cleaned flask. This procedure was repeated again after the tenth day, and fresh cuprous chloride (50 mg) was added. After 15 days of irradiation, the ratio of 2 to 1,5-cyclooctadiene was estimated to be 15:1 by glpc (30% Ucon oil nonpolar at 80°) and irradiation was stopped. The reaction mixture was distilled through a 60-cm spinning-band column and gave five fractions: (1) 0.7 g, bp 65–117°; (2) 0.5 g, bp 117–120°; (3) 4.6 g, bp 120–125°; (4) 10.2 g, bp 125–126°; (5) 3.1 g, bp 126–140°. Fractions 3 and 4 were estimated to be  $ca. 90\%$  2. Fraction 5 contained  $ca. 50\%$  2 and 50% of other  $C_8H_{14}$  isomers. The undistilled material (7.3 g) was discarded. The product could be further purified by refluxing with a solution of potassium permanganate (20 g) in 200 ml of water for 1 hr. Hydrocarbon 2 was recovered by steam distillation from the permanganate solution. Extraction of the water layer with *n*-pentane, followed by distillation, yielded 11.5 g (45%) of  $ca. 98\%$  pure 2. The infrared and nmr spectra agreed with the published data.<sup>3</sup>

**cis,anti,cis-Tricyclo[3.3.0.0<sup>3,7</sup>]octane (8).** From several preparations of 2, fractions equivalent to fraction 5 were collected and redistilled through a spinning-band column. A sample, bp 133–135°, was collected which was estimated to be 60% 8 by glpc (Ucon oil nonpolar). This fraction was further purified by preparative glpc (20% TCEP), yielding a sample of 8  $ca. 95\%$  pure. An nmr spectrum of 8 showed absorption bands centered at  $\tau$  7.9, 8.5, 8.98, and 9.45. A sample collected from the preparative glpc was analyzed.

**Anal.** Calcd for  $C_8H_{14}$ : C, 88.82; H, 11.18. Found: C, 88.72; H, 11.27.

A comparison of the nmr and infrared spectra of 8 with those of an authentic sample of *cis,anti,cis*-tricyclo[3.3.0.0<sup>3,7</sup>]octane,<sup>10,11</sup> obtained directly from Professor S. Winstein, showed the two compounds to be identical.

**Tricyclo[3.3.0.0<sup>3,7</sup>]octan-3-one (10).** Acetic acid (200 ml) and acetic anhydride (200 ml) were added to a 2-l. three-necked flask which was equipped with a Teflon stirrer and a thermometer. Chromium trioxide (40 g) was added to the solution with stirring, to prevent the formation of a solid mass. Heat was evolved as the chromium trioxide reacted with the acetic anhydride to form chromyl acetate. After being stirred for 1 hr, the reaction mixture was cooled to 0° and hydrocarbon 2 (27.8 g, 0.228 mole) of  $ca. 98\%$  purity was added dropwise at such a rate that the temperature remained below 3°. After being stirred for 15 hr at 0–3°, the reaction mixture was warmed slowly to 15° and then heated to 75°. Water (200 ml) was added to the reaction mixture and heating was continued at 100° for 2 hr. The reaction mixture was cooled and a solution of sodium hydroxide (360 g) in 500 ml of water (enough base to neutralize 90% of the acetic acid) was carefully added, with

cooling. The reaction mixture was diluted with water and extracted with ether six times. The ethereal solution was washed with saturated sodium bicarbonate solution until the washings remained basic, then with saturated sodium chloride solution, and was finally dried over sodium sulfate. The dried ethereal solution was distilled through a Podbielniak-type column to remove solvent, and the undistilled residue was redried over magnesium sulfate and finally distilled to yield ketone 10 and acetate 11 [bp 90° (32 mm)] in a 9:1 ratio as estimated by glpc (15% BDS at 120°). The yield of the ketone-acetate mixture was ca. 60% based on the amount of hydrocarbon consumed. A small sample of the product mixture was purified by zone freezing, and the ketone, whose melting point was slightly below room temperature, was analyzed. The infrared spectrum (neat) of 10 showed absorption maxima at 3.4, 5.69, 7.05, 7.80, 8.08, 8.30, 8.65, 9.00, 9.9, 11.20, 12.1, and 12.3  $\mu$ . The nmr spectrum exhibited singlets at  $\tau$  7.40(2), 7.78(2), 7.85(2), and 8.13(4).

Anal. Calcd for  $C_{14}H_{18}O$ : C, 78.65; H, 8.25. Found: C, 78.75; H, 8.21.

A semicarbazone, mp 199–200°, was prepared from 10 and recrystallized for analysis from absolute ethanol.

Anal. Calcd for  $C_{14}H_{18}N_2O$ : C, 60.31; H, 7.31; N, 23.45. Found: C, 60.45; H, 7.32; N, 23.50.

A 2,4-dinitrophenylhydrazone, mp 206–207°, was prepared from 10 and recrystallized for analysis from ethyl acetate.

Anal. Calcd for  $C_{14}H_{14}N_4O_4$ : C, 55.62; H, 4.67; N, 18.54. Found: C, 55.85; H, 4.85; N, 18.68.

**Tricyclo[3.3.0.0<sup>2,5</sup>]octan-3-ol (12).** Ketone 10 (885 mg, 7.25 mmoles) in anhydrous ether (10 ml) was added dropwise to a stirred suspension of lithium aluminum hydride (200 mg) in ether (25 ml). The reaction mixture was refluxed for 15 min, then cooled. Water (1 ml) was cautiously added. After being stirred for a further 30 min, the reaction mixture was filtered, and the precipitated salts were washed three times with ether. The ethereal solution was dried (magnesium sulfate) and filtered and the ether removed to yield a colorless oil (750 mg) which crystallized on standing. When the reaction product was sublimed, it yielded alcohol 12 (700 mg, 78%), mp 33–34°. The infrared spectrum (neat melt) showed absorption maxima at 3.0, 3.38, 3.47, 7.4, 7.8, 8.73, 9.10, 9.5, 9.7, 9.85, and 11.8  $\mu$ . The nmr spectrum showed a one-proton doublet ( $J = 7$  cps) at  $\tau$  5.58 (HCO), a singlet at  $\tau$  5.96, and a complex series of peaks from  $\tau$  7.45 to 8.6 (10 protons).

Anal. Calcd for  $C_{10}H_{16}O$ : C, 77.37; H, 9.74. Found: C, 77.47; H, 9.79.

**3-Acetoxytricyclo[3.3.0.0<sup>2,5</sup>]octane (11).** Alcohol 12 was acetylated in the usual way, by treatment with acetic anhydride and pyridine. After the usual work-up, the product was distilled through a Podbielniak-type column to yield 11, bp 65° (2.5 mm) (5.6 g, 75%). An infrared spectrum showed acetate absorption maxima at 5.67 and 8.00  $\mu$ .

Anal. Calcd for  $C_{10}H_{14}O_3$ : C, 72.26; H, 8.49. Found: C, 72.45; H, 8.53.

**Tricyclo[3.3.0.0<sup>2,5</sup>]octan-3-ol *p*-Toluenesulfonate (13).** Alcohol 12 (1.07 g, 0.0086 mole) and *p*-toluenesulfonyl chloride (1.82 g, 0.01 mole) were dissolved in pyridine (5 ml) at 0°. To the reaction mixture, after standing for 18 hr at 5°, was added a small piece of ice to destroy any remaining tosyl chloride. After remaining 30 min more at 5°, the reaction mixture was poured into ice. A white precipitate quickly formed. The white solid was filtered, washed with water, and dried to yield crude 13 (2.19 g). The crude 13 was recrystallized from 2-methylbutane (175 ml) by cooling the solution to –40°, which yielded the tosylate 13 as a white crystalline solid (2.03 g), mp 65–66°. A second crop of crystals (0.08 g), mp 64–65°, was obtained by removal of two-thirds of the solvent and cooling to –78°. The total yield of 13 was 2.11 g (88%). An infrared spectrum ( $CHCl_3$ ) showed bands at 6.22, 7.3–7.4, 8.52, and 10.3  $\mu$ , which correspond to a *p*-toluenesulfonate ester. A sample of 13, mp 65–66°, was recrystallized from 2-methylbutane for analysis.

Anal. Calcd for  $C_{15}H_{18}SO_3$ : C, 64.73; H, 6.52; S, 11.50. Found: C, 64.58; H, 6.62; S, 11.61.

**Kinetic Measurements of Acetolysis of 13.** The solvolysis reactions were run in anhydrous acetic acid solution that was 0.0549 *N* in sodium acetate. In both runs a specified amount of 13 was dissolved in 25.00 ml of the solvent, and samples were withdrawn from the reaction flask with a 1.00-ml pipet. The samples were titrated with 0.0328 *N* perchloric acid in acetic acid using bromophenol blue as indicator. The buret used had a 2-ml capacity with a micrometer drive that could be read to the nearest 0.001 ml; at 35.0°,  $k = 4.08 \times 10^{-4} \text{ sec}^{-1}$ ; at 50.0°,  $k = 2.52 \times 10^{-4} \text{ sec}^{-1}$ .

**Characterization of Acetolysis Products Derived from 13.** Tosylate 13 (5.6 g) was dissolved in a solution of glacial acetic acid (100 ml) which contained acetic anhydride (6 ml) and was 0.5 *N* in sodium acetate. The solution was heated at 95° for 0.5 hr; water (5 ml) was added, and heating was continued for 0.5 hr at 95°. The reaction mixture was cooled and poured into a separatory funnel, and water and ether were added. The aqueous layer was extracted four times with ether. The ethereal solution was washed with a saturated sodium carbonate solution until the washings remained basic, then with saturated sodium chloride solution. It was finally dried over magnesium sulfate. The ether was removed by distillation and the residue distilled, yielding three fractions: (1) 0.40 g, bp 41° (32 mm); (2) 1.82 g, bp 73° (5 mm); (3) 0.09 g, bp 73° (5 mm). Fraction 1 (20% yield over-all) was shown to be identical with bicyclo[3.3.0]octadiene-2,6 by infrared and nmr spectral comparison.<sup>22</sup> Fractions 2 and 3 (57% over-all) were shown to be acetates by their infrared spectra. They were reduced by lithium aluminum hydride in the usual fashion. The alcohols (ca. 1 g of the mixture) were separated by preparative glpc (30% Carbowax at 160°). The major product (70% of the alcohols; 40% over-all) was shown to be tricyclooctan-3-ol 12 by infrared comparison with an authentic sample. The minor alcohol (30% of the alcohols; 17% over-all) showed infrared absorption at 3.0 and 3.28  $\mu$ . The nmr spectrum showed bands centered at  $\tau$  4.67 (2), 6.25 (1), 6.66 (1), and a complex series of bands from  $\tau$  7.3 to 8.95. A glpc purified sample was analyzed.

Anal. Calcd for  $C_{10}H_{16}O$ : C, 77.38; H, 9.74. Found: C, 77.14; H, 9.72.

A sample of the unknown alcohol was hydrogenated over pre-reduced Adams' catalyst in methanol. The reaction mixture was poured into a separatory funnel and water and pentane were added. The aqueous layer was extracted twice with pentane. The pentane layer was dried over sodium sulfate and filtered, and the pentane removed, leaving an alcohol with infrared absorption maxima at 2.95, 6.87, 7.42, 9.0, 9.3–9.4, 9.83, 10.02, 10.2, and 10.67  $\mu$ . A phenylurethan was prepared from this alcohol and appeared as a white, crystalline solid, mp 71–76°. The white solid was recrystallized once from pentane, yielding a phenylurethan, mp 73–76° (lit.<sup>23</sup> *exo*-bicyclo[3.3.0]octan-2-ol phenylurethan, mp 75–76°). About 100 mg of the hydrogenated alcohol was oxidized in acetone by *N*-bromosuccinimide, according to the procedure of Cope.<sup>24</sup> A 2,4-dinitrophenylhydrazone was prepared from the crude ketone. This derivative was chromatographed over activity 1 alumina, using benzene as the eluent. The first 8 fractions were combined, the solvent was removed, and the somewhat purified product was rechromatographed on a silica gel thin layer plate, using pentane-ethyl acetate (95:5) as the eluent. The orange band, which had separated from a colorless band, was removed from the plate and the product extracted from the silica gel with chloroform. The chloroform was removed and the derivative crystallized upon standing. It was recrystallized once from ethanol to give a sample with mp 111–120°. The 2,4-dinitrophenylhydrazone of bicyclo[3.3.0]octan-2-one is reported to have a similar melting point range, 110–114.5°, attributed to a mixture of the *syn* and *anti* isomers.<sup>22,24</sup>

**3-Chlorotricyclo[3.3.0.0<sup>2,5</sup>]octane (9).** Tricyclooctane 2 (9.74 g, 0.090 mole) was added, in the dark, to a flask which contained a solution of benzene (107 g) and chlorine (ca. 3.5 g, 0.05 mole). The flask was then placed in a beaker of ice and set in the sunlight. After 1 min the color of the chlorine had disappeared. Nitrogen was bubbled through the reaction mixture to remove most of the hydrochloric acid. The solution was extracted once with a saturated sodium bicarbonate solution and finally dried over sodium sulfate. The reaction mixture was distilled through a spinning-band column (60 cm) and yielded hydrocarbon 2 (4.89 g) and chlorocarbon 9 (3.52 g, 55%), bp 68° (10 mm). An infrared spectrum (neat) showed absorption maxima at 3.39, 3.48, 6.91, 7.78, 7.98, 8.06, 9.15, 10.72, 10.92, 11.15, 13.8–13.9, and 14.0  $\mu$ . The nmr showed a complex one-proton doublet ( $J = \text{ca. } 7$  cps) at  $\tau$  5.5 (HCCl) and a complex series of peaks from  $\tau$  7.3 to 8.6 (10 protons).

Anal. Calcd for  $C_8H_7Cl$ : C, 67.37; H, 7.78; Cl, 24.85. Found: C, 67.20; H, 7.92; Cl, 24.71.

**Bromination of Tricyclo[3.3.0.0<sup>2,5</sup>]octane.** To a three-necked flask, equipped with stirrer, condenser, and dropping funnel, was added tricyclooctane 2 (2.9 g, 0.027 mole) and bromine (8 ml). The reaction mixture was heated, and at ca. 40° hydrogen bromide started to evolve. Heating was continued at 60° for 8 hr; the reaction mixture was diluted with carbon tetrachloride (25 ml). The reaction mixture was cooled and poured into a beaker which contained a solution of sodium sulfite. After the bromine had reacted, the reaction mixture was poured into a separatory funnel

layers were separated, and the organic layer was washed with a saturated sodium bicarbonate solution until the washings remained neutral.

The reaction mixture was dried over sodium sulfate. The solution was decanted from the drying agent and the carbon tetrachloride and 2 were removed by means of a rotary evaporator. The remaining oil (4.32 g) was distilled to give a pale yellow oil, bp 71° (0.5 mm) (1.79 g). An nmr spectrum showed a combination of absorption from  $\tau$  4.5 to 8.7. A sample was redistilled for analysis.

*Anal.* Calcd for  $C_8H_{11}Br$ : C, 36.12; H, 4.06; Br, 59.82. Found: C, 34.45; H, 4.36; Br, 61.08.

**Tricyclo[3.3.0.0<sup>1,4</sup>]octan-3-one Oxime (29).** To a 50-ml flask added ketone 10 (2.08 g, 0.017 mole), hydroxylamine hydrochloride (1.75 g, 0.019 mole), potassium hydroxide (1.8 g), water (1 ml), and methanol (5 ml). Concentrated hydrochloric acid was added to the reaction mixture, after standing at room temperature 2 days, until the mixture became acidic. The methanol was removed by means of a rotary evaporator, and the remaining mixture of oily oxime and water was extracted twice with ether. The ether solution was washed once with saturated sodium chloride solution, dried over magnesium sulfate, and filtered. The ether was removed by means of a rotary evaporator. The remaining oil (46 g) was sublimed and yielded oxime 29, mp 54–57.5° (2.21 g). The infrared spectrum ( $CCl_4$ ) showed absorption maxima at 3.2, 3.4, 5.88, 7.80, 8.05, 8.29, 8.97, 9.16, 10.6, 10.8, and 11.1  $\mu$ .

*Anal.* Calcd for  $C_8H_{11}NO$ : C, 70.04; H, 8.08; N, 10.21. Found: C, 70.25; H, 7.98; N, 10.08.

The starting material was not pure ketone 10 but a mixture of ketone 10 and acetate 11, then the best method for the purification of oxime was recrystallization from pentane. The impure oxime was dissolved in ca. 15 times its volume of pentane and cooled to 0°. An oil separated after 1 hr; the pentane was decanted. This oil and the pentane cooled to –40° for an additional 12 hr. The pentane was decanted from the crystalline oxime and the oxime was removed from the pentane by a stream of nitrogen. The yield was 70%.

**Tricyclo[3.3.0.0<sup>1,4</sup>]octylamine (30).** A solution of oxime 29 (0.059 mole) in anhydrous tetrahydrofuran (100 ml) was added to a stirred suspension of lithium aluminum hydride (10 g) in tetrahydrofuran (300 ml). The reaction mixture was stirred for 2 days. After cooling, the suspension was hydrolyzed by dropwise addition of water (25 ml), followed by stirring for an additional 30 min. The solution was filtered, and the precipitated inorganic salts were extracted by ether in a Soxhlet apparatus for 1 day. The combined tetrahydrofuran and ether solutions were dried over molecular sieves (Fisher Type 4A) and the solvent was distilled off through a Podbielniak column. The residue was distilled and yielded amine 30 (82%), bp 83° (32 mm). The infrared spectrum (neat) showed absorption maxima at 2.95, 3.0, 3.40, 3.47, 6.2, 6.81, 6.90, 7.40, 7.80, 9.13, and 11.1  $\mu$ . The nmr spectrum showed a complex series of peaks, characteristic of the 3-substituted derivatives of the tricyclooctane nucleus, from  $\tau$  7.7 to 9.0.

**Benzyliothiurea, mp 134–143°**, was prepared from 30. Repeated recrystallizations from ethanol and acetone–pentane gave a sample which was analyzed, despite its broad melting range (134–143°).

*Anal.* Calcd for  $C_{11}H_{15}N_2S$ : C, 69.74; H, 7.02. Found: C, 69.35; H, 7.12.

**N,N-Dimethylaminotricyclo[3.3.0.0<sup>1,4</sup>]octane (32).** To amine 30 (0.024 mole) was added, with cooling, formic acid (5.0 g) in methanol (5.5 g of a 33% solution). The reaction mixture was heated on a steam bath for several hours, cooled, and acidified with N hydrochloric acid. All volatile material was removed under reduced pressure, and the remaining oil made basic with sodium hydroxide. The aqueous mixture was extracted with ether and dried over magnesium sulfate and the ether removed by means of a rotary evaporator. The remaining colorless oil was distilled and yielded amine 32 (3.0 g, 80%), bp 74° (15 mm). The infrared spectrum showed absorption maxima at 3.55 and 3.61  $\mu$ , characteristic of the N,N-dimethyl grouping.

**Tricyclo[3.3.0.0<sup>1,4</sup>]octane-3-one Oxime (33a).** A sample of oxime 29, mp 178–178.5°, was prepared from 32 and recrystallized from ethanol.

*Anal.* Calcd for  $C_{10}H_{13}NO$ : C, 50.53; H, 5.30; N, 14.73. Found: C, 50.72; H, 5.33; N, 14.63.

**Tricyclo[3.3.0.0<sup>1,4</sup>]octyltrimethylammonium Iodide (33a).** A sample of oxime 29 (1.08 g, 0.0071 mole) in ether (20 ml) was added methyl iodide (2 ml) and potassium carbonate (0.25 g). The reaction mixture started to turn cloudy almost immediately and was let

stand at room temperature overnight. The precipitate that had formed was filtered, washed with ether, and recrystallized from ethanol–ether, yielding 33a (2.02 g, 95%), mp 234–243°. A sample, mp 245–247° dec, was recrystallized for analysis from ethanol–ether.

*Anal.* Calcd for  $C_{11}H_{15}NI$ : C, 45.23; H, 6.85; N, 4.76; I, 43.12. Found: C, 44.99; H, 6.70; N, 4.82; I, 43.18.

**B. Oxime 29 (12.0 g, 0.0879 mole) in tetrahydrofuran (100 ml)** was added to a stirred slurry of lithium aluminum hydride (10 g) in tetrahydrofuran (500 ml, freshly distilled from lithium aluminum hydride). The reaction mixture was refluxed for 2 days and cooled, and water (40 ml) was carefully added. The reaction mixture, after stirring for an additional hour, was filtered, and the precipitated inorganic salts were extracted by ether in a Soxhlet apparatus for 1 day. The combined tetrahydrofuran and ether solutions were dried over molecular sieves (Fisher Type 4A). The solution was decanted from the molecular sieves, and methyl iodide (8.1 ml, 0.088 mole) was added to the solution and let stand overnight. The solvent was distilled off through a Podbielniak-type column. The residue was transferred to a small flask and methanol (100 ml), methyl iodide (35 ml), and sodium carbonate (30 g) were added; the reaction mixture was then refluxed for 2 days. The methanol and methyl iodide were removed by means of a rotary evaporator and the remaining salts extracted four times with boiling chloroform (100-ml portions). The chloroform was removed by rotary evaporation, and the residue was recrystallized from ethanol–ether, yielding crystalline 33a (22.9 g, 83%).

**Tricyclo[3.3.0.0<sup>1,4</sup>]octene-3 (4).** Trimethylammonium iodide 33a (12.5 g, 0.040 mole) was dissolved in a solution of methanol (100 ml) and water (50 ml). To this solution was added freshly prepared silver oxide (0.050 mole), and the reaction mixture was stirred for 2 days at 35°. The reaction mixture was then filtered, and the silver salts were washed with three portions of methanol (20 ml). The combined filtrate and washings were distilled, in a nitrogen atmosphere, under reduced pressure. When the solvent had been removed, the syrupy residue was heated. Decomposition commenced at 95° (12 mm) and was complete at 120° (12 mm). To the products, which were collected in a flask cooled in a Dry Ice bath, was added pentane (5 ml). The reaction mixture was cooled in a freezer. After the water had frozen, the organic layer was decanted and the ice washed with pentane (5 ml). The combined pentane solution was dried over sodium sulfate. The solution was then distilled through an 8-in., spinning-band column and was cut into six fractions: (1) 0.0547 g, bp 63° (130 mm); (2) 0.616 g, bp 58° (110 mm); (3) 0.232 g, bp 86–108° (100 mm); (4) 1.15 g, bp 108–118° (100 mm); (5) 1.01 g, bp 118° (100 mm); (6) 0.807 g, bp 118° (100 mm). Fractions 1 and 2 were shown to be 4 (29% yield from 33a; 60% based on unrecovered amine 32) and fractions 3–6 were shown to be 32. The infrared spectrum of 4 showed absorption at 3.24, 3.37, 3.48, 6.44, 6.82, 7.65, 8.02, 8.3, 8.57, 11.15, and 14.7  $\mu$ . The infrared absorption band at 6.44  $\mu$  is tentatively assigned to the C=C stretching frequency.<sup>44</sup> The nmr spectrum ( $CCl_4$ ) showed a two-proton triplet ( $J = 2$  cps) at  $\tau$  3.93, a 2-proton pentuplet ( $J = 0.7$  cps) at  $\tau$  6.53, a two-proton triplet ( $J = 2$  cps) of pentuplets ( $J = 0.4$  cps) at  $\tau$  8.15, and a complex four-proton band centered at  $\tau$  8.27. A sample of fraction 1 was analyzed.

*Anal.* Calcd for  $C_8H_{10}$ : C, 90.51; H, 9.49. Found: C, 90.35; H, 9.50.

A small sample of 4 was hydrogenated over prerduced Adams catalyst in methanol. The methanol solution was extracted with water and pentane. The pentane layer was dried over magnesium sulfate. The pentane was distilled off and the residue was separated, by preparative glpc (30% TCEP), from the remaining solvent and shown to be tricyclo[3.3.0.0<sup>1,4</sup>]octane by glpc and infrared and nmr spectral comparisons.

The ultraviolet spectrum of 4 showed an absorption maximum at ca. 215  $m\mu$  (in isooctane) with an extinction coefficient of 2640; at 230  $m\mu$ , the extinction coefficient was 1730; at 240  $m\mu$ , it was 700; at 250  $m\mu$ , it was 150. The O–O band is centered at 250  $m\mu$  in this solvent. A spectrum was also run in the vapor phase. A very small drop of 4 was spaced in a 1-cm liquid cell and a spectrum of the vapor was taken. Vibrational fine structure could be seen on the electronic absorption envelope at 251, 246, 239, 237, 232, 227, 223, 220, 219, 215, 213.5, 212.2, 211.2, and 211.0  $m\mu$ . The extinction coefficients were not determined in the vapor phase spectrum.

(44) For a discussion of the relationship between C=C stretching frequencies and bond angles, see C. F. Wilcox and R. R. Craig, *J. Am. Chem. Soc.*, **83**, 3866 (1961).

The mass spectrum of 4 determined on a CEC 21-130A instrument at 70 ev showed a parent peak at *m/e* 106, a base peak at 78, and other intense peaks at 91, 39, and 105.

3-N,N-Dimethyltricyclo[3.3.0.0<sup>3,6</sup>]octylamino Oxide (34). To a 50-ml flask was added 32 (0.718 g, 4.75 mmoles), methanol (2 ml), and hydrogen peroxide (30%, 2 ml), and the reaction mixture was let stand at room temperature for 2 days. A small amount of platinum black was added to destroy any remaining hydrogen peroxide. The solvent was removed under reduced pressure, leaving a white solid (0.86 g). The amine oxide was recrystallized

from tetrahydrofuran to yield crystalline 34 (0.76 g, 95%), mp 104–106°, no dec.

Pyrolysis of Amine Oxide 34. Pyrolysis of the amine oxide 34 was accomplished by heating in a round-bottomed flask equipped with a capillary nitrogen inlet and connected through a short column to two traps in series, cooled in Dry Ice. The nitrogen pressure was reduced to 10 mm, and most of the amine oxide decomposition took place between 180 and 210°. An nmr spectrum of the crude volatile products showed that only about 5% was the hoped for tricyclocene 4, while the rest seemed to be aromatic.

## Aromatic Azapentalenes. I. Dibenzo-1,3a,4,6a-tetraazapentalene and Dibenzo-1,3a,6,6a-tetraazapentalene.<sup>1</sup> New Heteroaromatic Systems

R. A. Carboni, J. C. Kauer, J. E. Castle, and H. E. Simmons

Contribution No. 1168 from the Central Research Department, Experimental Station, E. I. du Pont de Nemours and Company, Wilmington, Delaware.

Received November 17, 1966

**Abstract:** The new heteroaromatic compounds, dibenzo-1,3a,6,6a-tetraazapentalene (III) and -1,3a,4,6a-tetraazapentalene (II), have been prepared in good yield by the thermal and photochemical decompositions of the *o*-azido phenyl derivatives of 1H- and 2H-benzotriazoles, respectively. The physical and spectral properties of these unusually stable pentalene analogs are described, as well as their structure determination. The mode of formation of the tetraazapentalene and the role of the annular nitrogen atoms in providing a  $4n + 2$   $\pi$  electron system are discussed.

In recent years, there has been great interest in formulating and demonstrating aromatic character for a variety of carbocyclic and heterocyclic systems.<sup>2</sup> Aromatic stability has been demonstrated in cyclopropenium, cyclopentadienide, benzene, tropylium, and cyclononatetraenide, as well as in nonalternant and hetero systems, such as ferrocene, tropolone, and azulene.<sup>3</sup> All of these compounds contain 2, 6, 10, etc.,  $\pi$  electrons and illustrate an extension of Hückel's argument that cyclic molecules having  $4n + 2$   $\pi$  electrons possess closed shells of electrons and large delocalization energies.<sup>4</sup>

The hydrocarbon pentalene, an 8  $\pi$  electron system, has never been synthesized despite repeated efforts.<sup>5</sup> Condensed pentalenes have been prepared and found to possess no special stability; for example, dibenzopentalene is reported to exhibit olefinic properties around the central pentalene nucleus, which undergoes polymerization, addition of bromine, etc.<sup>6b</sup>

(1) These compounds may be named as 5,11-dehydro-5H,11H-benzotriazolo[2,1-*a*] and 5,7-dehydro-5H,7H-benzotriazolo[1,2-*a*] benzotriazole, respectively. The trivial name of azapentalenes is employed in this and subsequent papers in order to call attention to the central rings, to which these systems owe so much of their properties.

(2) Excellent reviews of these topics have appeared recently. See, for instance: (a) "Non-Benzenoid Aromatic Compounds," D. Ginsberg, Ed., Interscience Publishers, Inc., New York, N. Y., 1959; (b) M. E. Vol'pin, *Russ. Chem. Rev.*, 29, 129 (1960).

(3) Leading references to recent works appear in E. A. LaLancette and R. E. Benson, *J. Am. Chem. Soc.*, 87, 1941 (1965).

(5) (a) J. W. Barrett and R. P. Linstead, *J. Chem. Soc.*, 611 (1936); (b) C. T. Blood and R. P. Linstead, *ibid.*, 2255, 2263 (1952); C. C. Chuen and S. W. Fenton, *J. Org. Chem.*, 23, 1538 (1958); (c) J. D. Roberts and W. F. Gorham, *J. Am. Chem. Soc.*, 74, 2278 (1952); (d) M. Gates and S. P. Malchick, *ibid.*, 79, 5546 (1957).

The azapentalenes are of special interest since their properties are governed to a striking extent by the orientation of the hetero atoms. Thus, azapentalenes

with pyridine-type nitrogens at the nonfused positions (e.g., 1–6 of compound I) in either or both rings contain 8  $\pi$  electrons and are expected to be nonaromatic.

Paul and Weise found that both 2,3-benzo-1-azapentalene and 5,6-benzo-1-azapentalene are brown, unstable materials which could not be isolated pure.<sup>6</sup>

Kato and Ohta<sup>8</sup> were unsuccessful in an attempt to prepare the 8  $\pi$  electron dibenzo-1,4-diazapentalene from diindole. Treibs<sup>9</sup> reported the preparation of this derivative through dehydrogenation of diindole; however, this work was recently reported<sup>10</sup> to be erroneous.

The preparation of the highly stable, heteroaromatic compound, dibenzo-1,3a,4,6a-tetraazapentalene (II), was described earlier.<sup>11a</sup> Recently, we have synthe-

new tetraazapentalene system, dibenzo-1,3a,6,6a-tetraazapentalene (III), which exhibits aromatic properties similar to II. Unlike azapentalenes which do not contain bridgehead nitrogen atoms, these tetra-

azapentalenes can only be represented as hybrids of a pair of charge-separated forms, e.g., IIa,b and IIIa,b. In each of these structures, two of the four nitrogen atoms, two of which occupy the bridgehead positions, contribute six electrons to the  $\pi$  system, and the parent structures may be considered as hybrids of their relationship with the isoelectronic pentalene and the carbocyclic analog, pentalene diene.<sup>12</sup> Other examples of aromatic azapentalenes containing nitrogens at the bridgehead have recently been reported.<sup>11b-f</sup>

This paper presents the synthesis, structure, and properties of II and III as well as a discussion of their relationship to each other.

## Results and Discussion

Dibenzo-1,3a,4,6a-tetraazapentalene (II) is a yellow, crystalline solid, mp 237–238°, which exhibits yellowish fluorescence when viewed under ultraviolet light. It is only weakly basic, being insoluble in dilute mineral acids but dissolves in concentrated sulfuric acid; however, it precipitates when the pale yellow acid solution is poured into water. The crystalline methiodide is formed very slowly on prolonged heating with methyl iodide, a reaction which is readily reversible at higher temperatures. Compound II has no detectable dipole moment in benzene solution.

The isomeric dibenzo-1,3a,6,6a-tetraazapentalene (III) is a colorless solid, mp 255°, which does not exhibit fluorescence in solution. Although this isomer is only weakly basic, it appears to be slightly more soluble than II in mineral acids and does not form a methiodide readily. Compound III has a dipole moment in benzene of 4.36 D.

These heteroaromatic systems are little affected by heating in solvents below 300° and can be sublimed unchanged at atmospheric pressure. Both are also unchanged after treatment with warm alkaline potassium persulfate.

Calorimetric measurements for these isomeric dibenzotetraazapentalenes show that the heat of formation of III is 10.5 cal/mole greater than that of II.<sup>13</sup>

The dibenzotetraazapentalenes exhibit an interesting variety of chemical reactions which reflect the dual pyrrole-pyridine nature of the annular nitrogen atoms. Thus, electrophilic substitution reactions were observed on both benzenoid and heterocyclic rings. These reactions and others of the tetraazapentalenes are described in separate papers.

The ultraviolet spectra of the two dibenzotetraazapentalenes show many of the characteristic similarities and differences that have been noted<sup>14</sup> between aromatic heterocyclics and their carbocyclic analogs. Both II and III exhibit three main regions of absorption in the ultraviolet spectrum. In this respect, they resemble the annularly condensed tetracyclic hydrocarbons, e.g., the benzophenanthrenes, such as chrysene. Principal absorptions of II and III are given in Table I with those of chrysene. The major regions of absorption are separated in the table, those in each group clearly forming a vibrational subsystem.

<sup>a</sup> W. V. Mayneord and E. M. F. Roe, *Proc. Roy. Soc. (London)* **A152**, 299 (1935).

The long-wavelength absorptions of the tetraazapentalenes are about 50 times more intense than the  $\alpha$  band of chrysene. Similar comparisons have been noted by Badger and his co-workers<sup>14</sup> for many aromatic azahydrocarbon-hydrocarbon combinations. It is noteworthy that the absorptions of 1,3a,4,6a-tetraazapentalene (II) show an appreciable shift to longer wavelengths compared to the 1,3a,6,6a isomer (III) or chrysene, particularly in the long-wavelength region. The spectrum of III also contains less fine structure than that of II.

**A. Dibenzo-1,3a,4,6a-tetraazapentalene (II).** This compound is prepared in excellent yield by the thermal or photochemical decomposition of *o,o'*-diazidoazobenzene (IV) (see Chart I). The yellow diazide IV, mp 116–117° dec, is formed in greater than 90% yield on treatment of tetraazotized *o,o'*-diaminoazobenzene (V) with 2 equiv of sodium azide. When a solution of IV in a high-boiling solvent, such as decahydronaphtha-

(14) G. M. Badger, R. S. Pearce, and R. Pettit, *J. Chem. Soc.*, 3199 (1951).

Chart I

lene or *o*-dichlorobenzene, is heated at 180°, 2 moles of nitrogen is smoothly evolved. From the cooled, concentrated mixture, long, yellow needles of II are precipitated.

It was found, however, that the nitrogen was liberated in two distinct stages, 1 mole at the surprisingly low temperature of 58° and the second mole at approximately 170°. Thus, when *o,o'*-diazidoazobenzene was heated in refluxing acetone or benzene for 2 hr, the orange-red color characteristic of the azo derivative disappeared. The crystalline product which was isolated in good yield still contained an azido group. The solid, mp 77–78°, was identified as 2-(*o*-azidophenyl)-2H-benzotriazole (VI).

The infrared spectrum of this material was quite similar to those of a number of 2-arylbenzotriazoles. An absorption was noted at approximately 10.3  $\mu$  in each of the 2(aryl)-2H-benzotriazoles prepared in this study. The spectrum of VI also contained characteristically strong peaks at 4.75  $\mu$  for the azido function. The structure of VI was confirmed by an independent synthesis in which *o,o'*-diaminoazobenzene was oxidized with cupric sulfate<sup>15</sup> in pyridine to form 2-(*o*-aminophenyl)-2H-benzotriazole (VII), mp 97–98°. Diazotization of VII followed by treatment with sodium azide gave a product, mp 77–78°, which was identical with VI.

When 2-(*o*-azidophenyl)-2H-benzotriazole was dissolved in decahydronaphthalene and heated to 160–170°, another mole of nitrogen was evolved and II was obtained in nearly quantitative yield. These transformations were also obtained when benzene solutions

of either the diazidoazobenzene or 2-(*o*-azidophenyl)-2H-benzotriazole were exposed to sunlight for several days.

The formation of 1,3a,4,6a-tetraazapentalene II and its intermediate products may be represented by the reaction scheme shown in Chart I. The azidophenylbenzotriazole VI may form by a concerted reaction involving rupture of the N–N<sub>2</sub> bond of the first azide in IV by light or heat with concomitant cyclization or by formation, at least incipiently, of the neutral, electron-deficient species (a). To be specific, this chemistry will be discussed in terms of nitrene intermediates, although no compelling evidence for this interpretation is yet in hand. A cyclization can then be effected by the transfer of electrons from the neighboring, electron-rich, azo link to the developing univalent nitrogen to form 2-(*o*-azidophenyl)-2H-benzotriazole (VI). In a similar manner, the decomposition of the second azide group may be accompanied by interaction between the electrons of N-1 or N-3 and the electrophilic nitrogen of the decomposing azide. The higher temperature required for the second cyclization may reflect the decreased availability of electrons on the triazole nitrogens.

The planar tetraazapentalene structure of II has been conclusively established by X-ray,<sup>16</sup> and all chemical evidence supports this conclusion. It is important to note that the dibenzotetraazapentalene II is a valence isomer of dibenzo-1,2,5,6-tetraazacyclooctatetraene (VIII), a structure that might have been anticipated to be capable of existence. This molecule could form on

decomposition of the azide VI by rupture of the N–N bond of the triazole followed by formation of a new bond between the azido nitrogen and the 1- or 3-nitrogen of the triazole. Compounds claimed to be derivatives of the simple tetraazacyclooctatetraene ring system have been described as high-melting, fluorescent solids of high thermal stability.<sup>11c,17</sup> Some of these derivatives were shown recently to be simple tetraazapentalene systems.<sup>11d,18</sup>

Of the three possible conformers of the tetraazacyclooctatetraene VIIa–c, only *trans*-VIIb and the planar VIIc structures are possible in view of the

observed zero dipole moment of the molecule. The proton nmr spectrum of II in deuterochloroform revealed a complex ABCD pattern containing at least 15

(17) R. Metzger, *Angew. Chem.*, **68**, 580 (1956).

(18) M. Brufani, W. Fedeli, G. Giacomello and A. Vaciago, *Chem. Ber.*, **96**, 1840 (1963).

each of which possessed fine structure. The  $\Delta m$  showed no tendency to change to a symmetric  $B_2$  pattern at higher temperatures (up to 225°). Tetraazacyclooctatetraene structures VIIIb and would be expected to have an  $A_2B_2$  spectrum and resemble naphthalene. On the other hand, the apentalene structure should belong to the more complex ABCD class, provided that a valence tautomerism of the following type does not occur with frequency exceeding the separation frequency of experiment (60 cps). Since the proton spectrum is

obtained over a wide temperature range, we conclude the product is best represented by structure II and, moreover, that no exchange as represented by the tautomerism occurs.

In order to obtain further evidence for the tetraazapentalene structure and its possible valence tautomerism, an analogous compound was prepared in which the benzene rings is replaced by a naphthalene system with fusion at the  $\alpha, \beta$  position.

The synthesis of the naphtho-benzo compound was carried out in a manner similar to that employed for the synthesis of II. 1-(*o*-Nitrophenylazo)-2-naphthylamine (X) was obtained by the reaction of 2-naphthylamine and *o*-nitrophenyldiazonium chloride in dilute

hydrochloric acid. This was converted *via* cupric sulfate-ammonia solution to 2-(*o*-nitrophenyl)-2H-naphtho[1,2-*d*]triazole (XI) in 83% yield. Reaction of the aminoazo compound X with thionyl chloride at 80° also gave a yield of naphthotriazole XI. Reduction to the corresponding aminophenyl-naphthotriazole XII was accomplished with iron powder and acetic acid (70% yield) and with alcoholic sodium sulfide (91% yield). Oxidation, followed by aqueous sodium azide treatment, yielded 2-(*o*-azidophenyl)-2H-naphtho[1,2-*d*]triazole (XIII) in 95% yield.

Meldola and F. Hughes, *J. Chem. Soc.*, 59, 372 (1891).

The developing nitrene intermediate derived from XIII by loss of nitrogen could now close at either of the naphthotriazole nitrogen atoms marked by arrows to give IXa and IXb. If the tetraazapentalene formulation of the nucleus is correct and if there is a large barrier for the valence tautomeric exchange, then we would expect to observe the formation of *two non-superimposable* isomers IXa and IXb. Formation of the naphthobenzotetracyclooctatetraene should give rise to but *one* isolable product.

Thermal decomposition of the azidophenyl-naphthotriazole in *o*-dichlorobenzene or decahydronaphthalene at 170–180° proceeded smoothly with evolution of 1 mole of nitrogen to yield a yellow, crystalline product, mp 190–200°. The solid exhibited yellow-green fluorescence under ultraviolet light, similar to that of dibenzotetraazapentalene II. Chemical analyses corresponded well for C<sub>16</sub>H<sub>10</sub>N<sub>4</sub>, despite the wide melting-point range. This suggested a mixture of at least two products of identical empirical formula. Chromatographic separation employing mixed solvents yielded two sharp-melting products, mp 212–213 (faster moving) and 243–245° (slower moving), in addition to an intermediate fraction composed of the two unseparated components. Each of the isomers analyzed correctly, and their infrared spectra showed strong similarities. A 1:1 composite of the pure isomers accounts for all of the peaks observed in the spectrum of the original, wide-melting solid.

These results clearly support the tetraazapentalene structure in preference to the tetraazacyclooctatetraene structure. Furthermore, no evidence for the interconversion of IXa and IXb could be obtained, since both are stable at their melting points.

It was of interest to determine which of the structures IXa and IXb was associated with the higher and the lower melting isomers, respectively. One method for accomplishing this was suggested by the action of lithium aluminum hydride on the tetraazapentalene nucleus.

When a solution of the dibenzotetraazapentalene II in tetrahydrofuran was treated with an excess of lithium aluminum hydride at 60°, cleavage of a N–N bond occurred with the formation, after hydrolysis, of 2-(*o*-aminophenyl)-2H-benzotriazole (VII). It is possible to rationalize this reductive ring cleavage by attack of a hydride ion at N-1 according to the scheme shown, fol-

lowed by hydrolysis to yield the benzotriazole derivative VII.

Similar treatment of each of the isomeric naphthobenzotetraazapentalenes IXa and IXb might, therefore, be expected to give different mixtures of triazoles XII and XIV, and XII and XV, respectively, as shown in Chart II. Identification of either mixture of products should determine the configuration of both isomers.

Samples of each pure isomer were treated with excess lithium aluminum hydride in tetrahydrofuran at

Chart II

60–70° for several hours. The excess hydride was destroyed, and the reaction products were isolated in each case. Infrared spectra of the product mixtures were compared with authentic composites of XII and XV which were prepared by independent syntheses.

As expected, the similarities in spectra for the two reaction mixtures presented some difficulties. This was augmented by the formation in each case of the common product, 2-(o-aminophenyl)-2H-naphtho[1,2-d]triazole (XII), as the major component. However, the very close similarity between a 3:1 synthetic mixture of XII and XV and the products from the low-melting isomer indicated that the latter possessed structure IXb. The infrared spectrum of the higher melting isomer's reduction products, though exhibiting many similarities to the synthetic mixture, nevertheless showed several variations including significant differences in the 10.6–11.2  $\mu$  region.

Attempted chromatographic separation of the reduction products of IXb led to the isolation of the more abundant naphthotriazole XII; however, the  $\beta$ -aminonaphthylbenzotriazole XV was not isolated in the pure state.

The preferential cleavage of IXa and b to give XII as the major component is not unexpected in view of its formation as the sole product from the oxidative cyclization of the diaminoazo derivative XVI with copper sulfate–pyridine.

**B. Dibenzo-1,3a,6,6a-tetraazapentalene (III).** This compound was prepared by the thermal decomposition of 1-(o-azidophenyl)-1H-benzotriazole (XXI) in a manner analogous to that employed for the preparation of II from VI (see Chart III). The isomeric tetraazapentalene (III) is a colorless, crystalline solid whose

Chart III

physical and chemical properties closely resemble of II. It differs from II in its spectral properties a having an appreciable dipole moment (4.36 D in zene at 25°). The large dipole moment is in a with the formulation of III as a mesoionic stru with unsymmetrically distributed charge.

The 1-(o-azidophenyl)-1H-benzotriazole (XXI), prepared from the corresponding amine XX which turn, was obtained from the nitrophenylbenzotri XVIII. This latter compound was prepared orig by the reaction of o-chloronitrobenzene with b triazole, as described by Vystřil, *et al.*,<sup>20</sup> We f however, that this procedure leads to a mixture o and 2H-o-nitrophenylbenzotriazoles (XVIII and in yields of 39 and 16%, respectively. The two is (XVIII and XIX) were separated by column matography. The structure of isomer XIX was fied by catalytic reduction to 2-(o-aminophenyl benzotriazole (VII). A more satisfactory synthe XVIII was achieved by diazotization of o-ami nitrodiphenylamine, in turn conveniently ava from o-phenylenediamine by a modification o procedure of Kehrmann and Steiner.<sup>21</sup>

**Structure of Tetraazapentalenes.** The elec structure and spectra of the tetraazapentalenes v discussed in more detail in a later paper.<sup>13</sup> Perha most striking aspect of II and III is their pron aromatic character as revealed in their thermody stability, chemical reactivity, and electronic sp Closely related to their stability is the question c ence isomerization with a tetraazacyclooctatetrae illustrated for the unsubstituted nucleus wher asterisks label the course of isomerization.

The azapentalenes Z and Z' are clearly equi when unlabeled and could be interconverted b opening to C<sub>1</sub> and/or C<sub>2</sub>. Experimentally, this not occur for the dibenzo derivatives and mean a large energy barrier separates Z and C<sub>1</sub> or C<sub>2</sub>.

(21) F. Kehrmann and G. Steiner, *Ber.*, 34, 3089 (1901).

all attempts in this laboratory and elsewhere<sup>11d,e</sup> to prepare tetraazacyclooctatetraenes have given tetraazapentalenes instead, it seems very likely that the latter structure is the more thermodynamically stable. In fact, the evidence thus far suggests that a tetraazacyclooctatetraene would go over exothermically and spontaneously to the corresponding tetraazapentalene.

In Z two nitrogens are pyridine-like and two pyrrole-like, so that the system contains 10  $\pi$  electrons. In molecular orbital language, the aromaticity of Z results from a closed decet of  $\pi$  electrons in a cyclic molecule which obeys Hückel's  $4n + 2$  rule. Alternatively, in valence-bond language, a high resonance energy is expected based on the observation that 12 *nonexcited* structures in the Pauling sense can be written along with a very large number of mono- and higher excited structures. The resonance should be particularly important, since many of the nonexcited structures, such as

are of comparable energy. The fact that only charge-separated structures can be written for the tetraazapentalenes seems to be intimately related to large resonance energies and aromaticity. In fact, calculations suggest that 10  $\pi$  electron azapentalenes which can be written without forced charge separation are less stable than corresponding isomers which require charge-separated structures.<sup>13</sup>

The relative stabilities of the 8  $\pi$  electron cyclooctatetraene structures and 10  $\pi$  electron pentalene structures can be deduced by considering the delocalization energy of planar cyclooctatetraene and of pentalene dianion. Hückel theory predicts delocalization energies of  $1.66\beta$  and  $2.46\beta$ , respectively, where  $\beta$  is the usual resonance integral for an ethylenic double bond. Even with the assumption of a fictitious planar cyclooctatetraene whose degenerate ground state has been neglected, the stabilization energy per  $\pi$  electron is larger in the 10  $\pi$  system ( $0.25\beta/\text{electron}$ ) than in the 8  $\pi$  system ( $0.21\beta/\text{electron}$ ).

Precisely the same relative stability is found in the nitrogen analogs. Hückel calculations were carried out for Z, C<sub>1</sub>, and C<sub>2</sub> employing reasonable parameters,<sup>13,22</sup> and it could be shown that delocalization is even more important in stabilizing the tetraazapentalenes than the carbon analog. It was also shown that the chemical reaction C<sub>1</sub> (or C<sub>2</sub>)  $\rightarrow$  Z is expected to be exothermic by a substantial degree, although accurate predictions cannot be made.

(22) A. Streitwieser, Jr., "Molecular Orbital Theory for Organic Chemists," John Wiley and Sons, Inc., New York, N. Y., 1961, p 135.

Explicit calculations also reveal that the molecular orbitals of the 1,3a,4,6a- and 1,3a,6,6a-tetraazapentalene systems are remarkably similar, and we conclude that the precise location of the nitrogen atoms in charge-separated tetraazapentalenes has only a minor effect on stability. These conclusions and those given above serve to support the view that tetraazapentalenes must be considered truly aromatic molecules.

## Experimental Section<sup>23</sup>

*o,o'*-Diaminoazobenzene (V). To a stirred mixture of 45 g (0.5 mole) of *o*-phenylenediamine and 2 l. of benzene was added 239 g (1.0 mole) of lead dioxide. After 1 hr the mixture was brought to reflux and maintained thus for 3 hr. The insoluble lead salts were removed by filtration and the deep orange filtrate was cooled. Concentrated hydrochloric acid (150 ml) was added to the latter with stirring, and the solid which precipitated was collected by filtration. The solid, suspended in cold water (300–400 ml), was treated with sodium hydroxide solution to a pH of approximately 9. The alkaline mixture was extracted with methylene chloride, and the extract was dried over magnesium sulfate, then evaporated to dryness. Recrystallization of the residue from benzene gave two crops of orange crystals, mp 133–134° (lit.<sup>24</sup> 133–134°). The yield was 20 g.

*o,o'*-Diazidoazobenzene (IV). A solution of 7 g (0.1 mole) of sodium nitrite in 40 ml of water was added dropwise to a stirred mixture of 8.6 g (0.04 mole) of *o,o'*-diaminoazobenzene, 60 ml of concentrated hydrochloric acid, and 80 ml of water at 0–2°. The temperature was maintained below 10° during the addition. Stirring was continued for an additional hour after the nitrite addition. Sodium azide (6.5 g, 0.1 mole) in 40 ml of water was slowly added to the diazonium solution at 5° with continued stirring. Nitrogen evolved, and the yellow diazide precipitated during the addition. The mixture was stirred for an additional 2 hr, then filtered to obtain the diazidoazobenzene (9.8 g, 93% yield), mp 110–111° dec.

*Anal.* Calcd for C<sub>12</sub>H<sub>8</sub>N<sub>6</sub>: C, 54.54; H, 3.05; N, 42.41. Found: C, 54.75; H, 3.31; N, 42.37.

2-(*o*-Aminophenyl)-2H-benzotriazole (VII). *o,o'*-Diaminoazobenzene (4.4 g, 0.02 mole) was dissolved in 50 ml of pyridine and treated with 12.8 g (0.08 mole) of copper sulfate added in portions with stirring. After 30 min at room temperature, the reaction mixture was heated at reflux for 2 hr, cooled, and poured into 4–5 volumes of cold water with stirring. The dark solid which separated was collected by filtration and washed with water. Two recrystallizations from ethanol and one from hexane with concomitant treatment with activated carbon yielded well-defined, yellow crystals of VII, mp 97–98°; yield, 65%.

*Anal.* Calcd for C<sub>12</sub>H<sub>10</sub>N<sub>4</sub>: C, 68.55; H, 4.79; N, 26.65. Found: C, 68.55; H, 4.98; N, 26.56.

The infrared spectrum contains a peak at 10.3  $\mu$ , which was found in all 2-aryl-2H-benzotriazoles examined in this investigation. The ultraviolet spectrum in ethyl alcohol exhibits absorption maxima at 357 m $\mu$  ( $\epsilon$  9700), 296 (12,000), 268 (6400), and 229 (20,000).

2-(*o*-Azidophenyl)-2H-benzotriazole (VI). A solution of *o,o'*-diazidoazobenzene (5 g) in acetone or benzene was heated at reflux for 2 hr. One mole of nitrogen evolved, and the orange color was discharged. The solvent was removed by distillation, and the crystalline residue was recrystallized from petroleum ether or aqueous acetone (70% yield). The light yellow needles melted at 78–79°.

*Anal.* Calcd for C<sub>12</sub>H<sub>8</sub>N<sub>6</sub>: C, 61.01; H, 3.41; N, 35.58. Found: C, 61.04; H, 3.65; N, 35.94.

When a benzene solution of the diazidoazobenzene was exposed to sunlight for 3 days, a crystalline product was isolated, mp 76–77°, whose infrared spectrum was identical with that of the product

(23) All melting points are corrected. Nmr spectra were obtained with Varian HR-60 and A-60 spectrometers. Saturated deuteriochloroform solutions with tetramethylsilane as an internal standard were used unless otherwise noted. Infrared spectra in potassium bromide wafers were determined with a Perkin-Elmer 21 spectrometer. Ultraviolet spectra were determined in ethanol. Dipole moments were determined by Mr. C. Wortz in benzene solution at 25° using a Type DM-01 Dipol-meter (Wissenschaftlich-Technische Werkstätten Weilheim O.B., Germany).

(24) R. Willstätter and A. Pfannenstiel, *Ber.*, 38, 2348 (1905).

described above. The presence of an azido group was clearly indicated by the strong absorption at  $4.75 \mu$  in the infrared spectrum; a band at  $10.3 \mu$  is associated with the 2H-triazole structure.

**Dibenzo-1,3a,4,6a-tetraazapentalene (II).** (A) From *o,o'*-Diazidoazobenzene (IV). The diazide (8.2 g, 0.031 mole) in 700 ml of decalin was gradually heated to  $175^\circ$  with stirring. Nitrogen evolution occurred at approximately  $60^\circ$  with discharge of the orange azo color. At  $170^\circ$ , nitrogen was again evolved. The temperature was maintained at  $175$ – $185^\circ$  for 2–3 hr, and the solution was concentrated to approximately 100 ml. The dibenzotetraazapentalene II separated as long, yellow needles (6.0 g, 93% yield) which melted at  $237$ – $238^\circ$ ;  $\nu_{\max}$  3070, 1615, 1580 (w), 1490, 1435, 1390, 1330, 1253, 1248, 1237, 1004, 997, 943, 937, 838 (w), 832 (w), 812, 747, and  $731 \text{ cm}^{-1}$ .

*Anal.* Calcd for  $\text{C}_{15}\text{H}_8\text{N}_4$ : C, 69.22; H, 3.87; N, 26.91; mol wt, 208. Found: C, 69.06; H, 3.99; N, 26.92; mol wt, 221.

(B) From 2-(*o*-Azidophenyl)-2H-benzotriazole (VI). The benzotriazole derivative VI in decalin was heated at  $175$ – $185^\circ$  for 2–3 hr in the manner described above. Compound II was obtained in 95% yield.

When a benzene solution of VI was exposed to sunlight for 10 days, a yellow, crystalline product precipitated, mp  $236$ – $237^\circ$ , whose infrared spectrum was identical with that of II from the thermal method.

**Lithium Aluminum Hydride Reduction of Dibenzo-1,3a,4,6a-tetraazapentalene (II).** A solution of 2.0 g of II in 200 ml of tetrahydrofuran was added slowly to a suspension of 5 g of lithium aluminum hydride in 75 ml of tetrahydrofuran. The mixture was stirred at  $25^\circ$  for 1 hr and was heated at reflux for 4 hr. The cooled mixture was carefully poured into cold water, and the organic products were extracted with methylene chloride. Evaporation of the solvent yielded 2-(*o*-aminophenyl)-2H-benzotriazole (VII), identical in chemical and spectral properties with the material described above.

**1-(*o*-Nitrophenylazo)-2-naphthylamine (X).** Compound X was prepared by the method of Meldola and Hughes<sup>19</sup> by diazotizing reprecipitated *o*-nitroaniline (27.6 g, 0.2 mole) with 13.0 g (0.2 mole) of sodium nitrite, filtering, and adding the diazonium solution to a cold, stirred solution of 2-naphthylamine (25 g, 0.18 mole) in dilute hydrochloric acid. The mixture was stirred for 1 hr and filtered to collect the dark solid (yield, 48 g). Recrystallization from acetic acid yielded lustrous, bronze-like crystals, mp  $202$ – $202.7^\circ$  (lit.<sup>19</sup>  $198^\circ$ ).

**2-(*o*-Nitrophenyl)-2H-naphtho[1,2-*d*]triazole (XI).** Method I. A mixture of 7.5 g of azo derivative X in 75 ml of pyridine and 20 g of anhydrous  $\text{CuSO}_4$  was refluxed with rapid stirring for 4 hr. The cooled reaction mixture was poured into four volumes of water and filtered to obtain a reddish solid (7.2 g). Recrystallization from 225 ml of ethanol yielded a crop of yellowish crystals (5.5 g). An additional 0.75 g was obtained on dilution of the mother liquor with water (total yield 83%). The product melted at  $121$ – $122^\circ$ .

**Method II.** To a mixture of the azo compound X (5 g) in 50 ml of benzene was added 3.0 g of thionyl chloride. The mixture was heated at reflux with stirring for 18 hr. The brown-yellow mixture was evaporated to dryness, and the solid residue was recrystallized from 100 ml of ethanol to yield 3.5 g (70%) of pale yellow solid. An additional alcohol recrystallization yielded almost colorless, transparent plates, mp  $121.8$ – $122.2^\circ$ . The infrared and ultraviolet spectra of this product were identical with the product obtained in method I.

*Anal.* Calcd for  $\text{C}_{14}\text{H}_{10}\text{N}_4\text{O}_2$ : C, 66.20; H, 3.48; N, 19.30. Found: C, 66.03; H, 3.33; N, 19.58.

**1-(*o*-Aminophenylazo)-2-naphthylamine (XVI).** An attempt to form the 2-(2'-amino-1'-naphthyl)-2,1,3-benzotriazole (XV) by reductive cyclization of 1-(*o*-nitrophenylazo)-2-naphthylamine (X) gave, instead, the diaminoazo derivative XVI by simple reduction.

To a warm, stirred mixture of 7 g (0.024 mole) of X in 210 ml of ethanol was added a solution of 24 g (0.1 mole) of sodium sulfide nonahydrate. The mixture was heated at reflux for 3 hr. An additional 12 g of the sodium sulfide was added after the first hour. The cooled mixture was filtered to collect the reddish crystals (3.5 g). Dilution of the filtrate with 500 ml of water yielded an additional 2 g of product (total yield 87%). A sharp melting point was not achieved despite several recrystallizations from various solvents. However, the structure of the product was ascertained by spectra and by chemical reactions described below.

**2-(*o*-Aminophenyl)-2H-naphtho[1,2-*d*]triazole (XII).** The amino derivative XII was prepared by treating the corresponding nitro compound XI with iron powder in acetic acid (yield, 70%) and by

reduction with sodium sulfide (yield 91%). After recrystallization from ethanol, XII melted at  $126$ – $127^\circ$ .

*Anal.* Calcd for  $\text{C}_{14}\text{H}_{10}\text{N}_4$ : C, 73.82; H, 4.64; N, 21.53. Found: C, 74.09; H, 4.65; N, 21.72.

Compound XII shows a marked blue fluorescence when viewed under ultraviolet illumination, both in solution and in the solid state. The *N*-acetyl derivative XVII was prepared in 86% yield by heating with acetic anhydride. After recrystallization from ethanol, the melting point was  $159.2$ – $160.6^\circ$ .

*Anal.* Calcd for  $\text{C}_{16}\text{H}_{14}\text{N}_4\text{O}$ : C, 71.50; H, 4.67; N, 18.53. Found: C, 71.29; H, 5.27; N, 18.35.

**2-(*o*-Azidophenyl)-2H-naphtho[1,2-*d*]triazole (XIII).** The 2-(*o*-aminophenyl)-2H-naphtho[1,2-*d*]triazole (XII) (13 g, 0.05 mole) was diazotized with a solution of 4.5 g (0.065 mole) of sodium nitrite in 30 ml of water. The mixture was stirred for 1 hr, during which a yellow solid separated. An aqueous solution of 4.5 g (0.07 mole) of sodium azide was added dropwise at  $5^\circ$  with continued stirring. No immediate evolution of gas was apparent. However, after 10 min gas evolution became quite evident with accompanying foam formation. After 1.5 hr, the bright yellow color was discharged. The cream-colored, solid azide was collected by filtration and recrystallized from 600 ml of ethanol, mp  $124.2$ – $124.8^\circ$  dec, yield, 13.6 g (95%).

*Anal.* Calcd for  $\text{C}_{16}\text{H}_{10}\text{N}_6$ : C, 67.12; H, 3.52; N, 29.36. Found: C, 67.42; H, 3.72; N, 29.14.

**$\alpha,\beta$ -Naphthobenzotetraazapentalenes (IXa,b).** The azido compound XIII (5.8 g, 0.02 mole) was heated in 200 ml of decalin at  $180^\circ$  for 2 hr with stirring. The color deepened to a brownish yellow during this period. The hot solution was treated with activated carbon, filtered, and allowed to cool slowly. A total of 3.4 g (65%) of IXa,b was obtained in two crops, mp  $192$ – $220^\circ$ .

*Anal.* Calcd for  $\text{C}_{18}\text{H}_{10}\text{N}_4$ : C, 74.40; H, 3.90; N, 21.70. Found: C, 74.14; H, 4.08; N, 22.13.

This mixture was subjected to chromatography through neutral Woelm alumina, using chloroform and eventually chloroform-methylene chloride as the developing solvents. The faster moving fraction was predominantly the lower melting isomer IXb, the intermediate fractions were mixtures, and the later fractions contained primarily the high-melting isomer IXa. Recrystallization of the lower and higher melting fractions gave yellow crystals, mp  $211.5$ – $212.5$  and  $244.5$ – $245^\circ$ , respectively.

*Anal.* Found (lower melting isomer): C, 73.90; H, 4.14; (higher melting isomer) C, 74.26; H, 4.03.

Comparison of the infrared spectra of the two isomers showed several differences in the fingerprint region. However, all of the peaks encountered in the spectrum of the original isomer mixture are accounted for by the spectra of the pure isomers.

**Lithium Aluminum Hydride Reduction of the Low-Melting Isomer (IXb).** A mixture of 0.300 g of the low-melting naphthobenzotetraazapentalene isomer in 25 ml of tetrahydrofuran was treated with a filtered solution of lithium aluminum hydride (excess) in tetrahydrofuran. The mixture was stirred at  $25^\circ$  for 30 min, at reflux for 1 hr, then overnight at room temperature (in a second run, the reaction mixture was refluxed for 5 hr with similar results). The now deeply colored mixture was treated with ethyl acetate, then with water to destroy excess hydride. The mixture was made acid with hydrochloric acid, poured into water, then again made alkaline. The mixture was extracted twice with ether and the latter dried over sodium sulfate, then evaporated to dryness, yielding an oily residue. Comparison of the infrared spectrum of this product with that of a 3:1 synthetic mixture of XII and XV showed that they were almost identical.

Chromatographic separations on Woelm neutral alumina employing ether, ether-methylene chloride, methylene chloride, and methylene chloride-ethyl acetate yielded 2-(*o*-acetamidophenyl)-2H-naphtho[1,2-*d*]triazole (XVII) as a crystalline solid which was identical with an authentic sample. Attempts to isolate the expected minor component XV were not successful.

*Note!* Acetylation of the amine apparently occurred during chromatographic development with ethyl acetate. In one run, a fast-moving component was isolated from a methylene chloride-ethyl acetate fraction and appeared to have a nonamidic N-H group. This material, which may have been the product of incomplete reduction, did not appear to be either of the expected products.

**Lithium Aluminum Hydride Reduction of the High-Melting Isomer IXA.** This reduction was carried out as described for the low-melting isomer (above). The oily residue isolated from this reaction showed some significant differences from the authentic composite in infrared spectrum.

**Nitrophenyl)-1H-benzotriazole (XVIII).** (A) From Benzotriazole. In this modification of the procedure of Vystřil, *et al.*,<sup>30</sup> 119.1 g of 1H-benzotriazole, 125 g of powdered sodium and 0.5 g of cupric acetate was placed in a 500-ml three-neck flask immersed in an oil bath held at 220–230°. The flask was equipped with a magnetic stirrer and a short distilling column. After a period of 40 hr, 27 ml of acetic acid was collected. The product was subjected to steam distillation to remove excess nitrobenzene. The viscous, black residue was rinsed with water and extracted with a mixture of benzene and methylene chloride. The extract was filtered and dried over magnesium sulfate. The methylene chloride was removed under reduced pressure, the benzene solution remaining was eluted with benzene through a column of chromatographic grade silicic acid contained in a 125-mm diameter, sintered-glass funnel. After a forerun containing o-nitrobenzene, a fraction containing 37.5 g (16%) of 2-(o-nitrophenyl)-2H-benzotriazole (XIX) was collected (ca. 1500 ml of solvent was required; see below). The column was then eluted with 1.0 ml of methylene chloride; this yielded 95 g (39%) of 1-(o-nitrophenyl)-1H-benzotriazole (XVIII), mp 118.9–120° (lit. mp 118°<sup>34</sup>).

**From o-Amino-o'-nitrodiphenylamine.** A mixture of 250 g of diphenylenediamine, 500 g of o-chloronitrobenzene, and 2 l. of absolute alcohol was mechanically stirred and heated to reflux in an oil bath for 3 days. The mixture was then subjected to distillation, and the nonvolatile residue was extracted with a 4 l. of chloroform. The extract was filtered, water washed, dried over magnesium sulfate. Solvent was removed under reduced pressure, and the residue was recrystallized from about 100 ml of alcohol to yield 305 g (58%) of o-amino-o'-nitrodiphenylamine in two crops, mp 106–107° (lit.<sup>31</sup> mp 103°).

A solution of 236 g of this product in 240 ml of acetic acid, water, and 1 l. of alcohol was poured onto 1500 g of crushed ice. A solution of 100 g of sodium nitrite in 200 ml of water was added at once while stirring. The mixture was stirred overnight. The solid was separated by filtration, washed with water, suction dried, and recrystallized to yield 223 g (90%) of 1-(o-nitrophenyl)-1H-benzotriazole, whose infrared spectrum was identical with that of the product obtained by method A.

**Nitrophenyl)-2H-benzotriazole (XIX).** The crude chromatographic product described above was eluted with methylene chloride from a column of Woelm neutral alumina and recrystallized from ethanol to yield white crystals melting at 132.8–133.8°;  $\nu_{\max}$  14,710, 290 (13,830), and 222 (25,000). Calcd for  $C_{13}H_8N_4O_2$ : C, 60.00; H, 3.36; N, 23.33. Found: C, 59.70; H, 3.46; N, 23.03.

Structure XIX was verified by reduction to the corresponding amine using hot, aqueous, ethanolic sodium sulfide solution. The amine (mp 93.5–94°) was identical (mixture melting point, infrared spectrum) with the 2-(o-aminophenyl)-2H-benzotriazole described above.

**Aminophenyl)-1H-benzotriazole (XX).** A solution of 25.7 g of II in 400 ml of ethanol was hydrogenated at 3 atm using 0.2 g of platinum oxide catalyst. The solution was filtered and evaporated to dryness to yield a tan solid, which was recrystallized from 180 ml of 95% alcohol to yield 16 g of 1-(o-aminophenyl)-1H-benzotriazole. A second crop of 2.9 g was obtained by evaporation of the solvent to a final volume of 50 ml. A portion recrystallized from ethanol melted at 132–132.4°;  $\lambda_{\max}$  287 m $\mu$  ( $\epsilon$  5780) and 242 (15,700);  $\nu_{\max}$  3410, 3320, 3200, 1622, 1570, 1465, 1452, 1314, 1290, 1268, 1243, 1182, 1160, 1122, 1080, 1040, 948, 853, 785, 762, and 692  $\text{cm}^{-1}$ .

**Anal.** Calcd for  $C_{12}H_{10}N_4$ : C, 68.55; H, 4.79; N, 26.61. Found: C, 68.64; H, 4.85; N, 26.75, 26.95.

**1-(o-Azidophenyl)-1H-benzotriazole (XXI).** A solution of 11.6 g of XX in 40 ml of hydrochloric acid was placed in a beaker equipped with a stirrer and immersed in an ice bath, and 60 g of crushed ice was added, followed by the dropwise addition of a solution of 3.9 g of sodium nitrite in 25 ml of water at 0–3°. After addition was complete, the solution was filtered into an ice-cooled flask, and a solution of 3.8 g of sodium azide in 25 ml of water was added dropwise while the reaction temperature was maintained at 0–5°. (Some ether was added to suppress foaming.) The reaction mixture was stirred overnight, and the solid product was collected by suction filtration and water washed. The crude 1-(o-azidophenyl)-1H-benzotriazole weighed 12.4 g (99%) and was used in the next step without further purification. A portion recrystallized from hexane melted at 84.6–85°;  $\lambda_{\max}$  254 m $\mu$  ( $\epsilon$  18,600), 235 (14,300), and 285 (sh) (680).

**Anal.** Calcd for  $C_{12}H_8N_6$ : C, 61.01; H, 3.42; N, 35.58. Found: C, 61.52; H, 3.66; N, 36.07.

**Dibenzo-1,3a,6,6a-tetraazapentalene (III).** A solution of 12.4 g of XXI in 30 ml of o-dichlorobenzene was added dropwise to 20 ml of refluxing o-dichlorobenzene heated with an oil bath. The solution was heated at reflux for 3 hr after addition was complete. Activated charcoal was added, and the mixture was filtered hot. On cooling, it deposited 8.13 g (74%) of crude III as grayish white needles. The product was purified by continuous elution with methylene chloride through a bed of Woelm neutral activated alumina. A heavy-solvent liquid-liquid extractor was found to be convenient for this purification. A layer of ca. 30 g of alumina was placed on top of a layer of glass wool in the bottom of the apparatus. The crude azapentalene was placed on top of the alumina and was slowly eluted through the alumina by the condensed vapors of refluxing methylene chloride. A portion of the product recrystallized from ethanol melted at 254.8–255.2°.

**Anal.** Calcd for  $C_{12}H_8N_4$ : C, 69.22; H, 3.88; N, 26.91. Found: C, 69.30; H, 3.88; N, 26.97; dipole moment: 4.36 D (0.002 M in benzene at 25°).

Three crystalline forms of the product could be obtained which differed somewhat in infrared spectrum. These were converted to the same form by melting and cooling;  $\nu_{\max}$  3070, 1515, 1490, 1460, 1450, 1430, 1390, 1325, 1310 (w), 1290, 1253, 1155, 1148, 1121 (w), 1090 (w), 1030, 1005 (w), 963, 930, 898 (w), 870 (w), 842 (w), 745, 730, and 724 (sh)  $\text{cm}^{-1}$ .

# Aromatic Azapentalenes. II. Reactions of Monobenzo- and Dibenzo-1,3a,4,6a-tetraazapentalenes<sup>1</sup>

R. A. Carboni, J. C. Kauer, W. R. Hatchard, and R. J. Harder

Contribution No. 1169 from the Central Research Department, Experimental Sta E. I. du Pont de Nemours and Company, Wilmington, Delaware.

Received November 17, 1966

**Abstract:** The reactions of dibenzo-1,3a,4,6a-tetraazapentalene (I) with a variety of reagents are described. The directive influence of the tetraazapentalene nucleus on electrophilic substitution reactions at the benzene rings is discussed. Ring-opening reactions of I with peracetic acid, lithium aluminum hydride, and cuprous cyanide give 2-phenylbenzotriazole derivatives. Monobenzo-1,3a,4,6a-tetraazapentalenes have been prepared, and the physical and chemical properties of these compounds are described.

The nitrogen-containing analogs of pentalene, the azapentalenes, are represented by replacement of the ring carbon atoms (with any associated hydrogen atoms) by nitrogen atoms. Placement of the annular nitrogens at nonfused positions gives azapentalenes containing 8  $\pi$  electrons. However, when both fused positions are occupied by nitrogen, the molecules possess electronic configurations similar to those of pentalene dianion or naphthalene. The preparation of dibenzo-1,3a,4,6a-tetraazapentalene (I) as well as the isomeric 1,3a,6,6a-tetraazapentalene was described previously.<sup>2,3</sup>

The heteroaromatic molecule I may be formally represented by a series of charge-separated structures Ia-c.

The chemical and physical properties of the dipolar tetraazapentalene might be expected to reflect a structure which lies between neutral naphthalene and pentalene dianion.<sup>4</sup> This paper describes some of the chemical and physical properties of I as well as those of monobenzo-1,3a,4,6a-tetraazapentalene.

**Electrophilic Substitution.** Dibenzo-1,3a,4,6a-tetraazapentalene (I) undergoes a number of facile electrophilic substitution reactions with and without disruption of the tetraazapentalene nucleus.

Treatment of I with chlorine or bromine in acetic acid or chloroform readily gave the dihalogenated derivatives IIIa,b in good yields. When I was treated with N-bromosuccinimide in acetonitrile, the monobromo

(1) These compounds may be named 1,5-dehydrotriazolo[2,1-a]benzotriazole and 5,11-dehydrobenzotriazolo[2,1-a]benzotriazole, respectively. The tetraazapentalene nomenclature is employed in this and subsequent papers to emphasize the role of the annular nitrogens of the central rings in providing the unusual properties of this novel system. The following numbering system has been adopted in this paper.

compound IIb was produced in 70% yield, together with a small quantity (5–10%) of dibromo derivative. Chromatography on alumina gave no evidence of tional monobromo isomers. Further bromination of this product with bromine in chloroform gave a dibromo product. A similar treatment of I with N-chlorosuccinimide in acetonitrile was less successful, yielding a mixture of monochloride IIa, dichloride IIIa, and some unre-

I. Nitration at 5° with 70% nitric acid gave a mixture of dinitro derivatives, from which the predominant dinitro derivative IIIc, mp 352°, was isolated. These dinitro products exhibit strong yellow-green fluorescence in solution. When I was treated with 90% nitric acid, the tetranitro derivative IIIe (mp 410° dec) was obtained in excellent yield. Surprisingly, the tetranitro product was also formed when I was heated with aqueous nitric acid at 60°. The latter is normally employed as an oxidizing rather than a nitrating medium. When I was treated at 0° with 25% aqueous nitric acid, a mononitro product formed. Evidence for only one mononitro isomer in the crude product was found.

Treatment of I with chlorosulfonic acid at 90° produced the bis(sulfonyl chloride) IIIf in 50% yield. This compound was relatively resistant to water but reacted with amines and ammonia to give the expected sulfonamides.

Stannous chloride reduction of the mono- and dibenzotetraazapentalenes gave incomplete conversion to the corresponding amines Id and IIId, respectively, thus rendering difficult the purification of the products. However, catalytic hydrogenation in methanol with 10% palladium on carbon gave the desired amines which were more readily purified.

**Position of Electrophilic Substitution.** The halogenation of I occurs to a very large extent at the 2-

ion(s) in the benzene rings, *i.e.*, *para* to the non-nitrogens. The position of the bromine atom in I was established through conversion of 2-(5'-bromodiphenyl)-2H-benzotriazole (V) to the corresponding tetraazapentalene derivative which was identical with IIIb. The location of the two bromo groups at 2 and 8 positions in IIIb was established by con-

on of the latter with cuprous cyanide to 2-(2'-ophenyl)-5,5'-dicyano-2H-benzotriazole (VIa) and

to the diamide VIIb, which was identical with a  
le prepared by an independent route. This reac-  
is discussed later. If the quasiquinoid intermedi-  
VIIa and VIIb are accepted as models for the

ition states during electrophilic attack, these tran-  
1 states should be more stable than those for sub-  
sion at the 1,3 (7,9) positions (VIIIa,b). In the latter  
only limited charge delocalization is possible.  
substitution of I would similarly be expected to  
r at the 2, 4, 8, and 10 positions. It is unlikely  
the substitution reactions would be complicated by  
nation of the ring nitrogens in view of their weakly  
character and the mild conditions employed (*e.g.*,  
aqueous nitric acid).

e preferential substitutions at the 2, 4, 8, and 10  
ions are also in accord with an approximate charge  
bution calculated by molecular orbital methods.<sup>5</sup>

Y. T. Chia and H. E. Simmons, *J. Am. Chem. Soc.*, **89**, 2638

The apparent absence of isomers in the monobromina-  
tion and -nitration is surprising since the calculated  
charge densities at C-2 and C-4 are close, and the localiza-  
tion energies associated with attack at either position  
might be expected to be comparable.

Tetracyanoethylene (TCNE), a weak electrophile  
which is capable of undergoing substitution reactions  
with reactive aromatic systems,<sup>6</sup> such as dimethyl-  
aniline, phenol, etc., did not give the tetracyanoethyl  
or tricyanovinyl derivative of I. Rather, an aceto-  
nitrile solution containing I and TCNE gave a deep  
color associated with formation of a  $\pi$  complex (see  
below).

**Nucleophilic Displacement Reactions on Substituted  
Tetraazapentalenes.** When a solution of tetranitro-  
dibenzotetraazapentalene (IIIe) in dimethylformamide  
was treated with azide ion, a diazidodinitro derivative  
was produced. Milder conditions yielded the 2- (or 4-)  
monoazidotrinitro derivative.

The dinitrodibenzotetraazapentalene (IIIc) also was  
attacked by azide ion; however, the reaction proceeded  
more slowly.

As in the case of electrophilic attack, nucleophilic  
substitution might be expected to occur with relative  
ease at the 2,4 or 8,10 positions in tetraazapentalenes.  
Attack at these positions probably involves anionic  
intermediates which may serve as models for the rate-  
determining transition state. One important con-  
tributing resonance structure for such anions may be  
formulated as IXa. Corresponding stabilization of the  
transition state for substitution at the 1,3 or 7,9 posi-  
tions is not possible.

**Reaction with *n*-Butyllithium.** Compound I under-  
goes a metalation reaction with *n*-butyllithium. Thus,  
when I was treated with *n*-butyllithium, followed by  
methyl iodide, a bright yellow crystalline product was  
obtained which analyzed correctly for the monomethyl  
derivative despite a broad melting point range. The  
strong resemblance of the infrared and ultraviolet spec-  
tra of the methyl derivative to those of the parent com-  
pound indicated little alteration in the electronic sys-  
tem, *i.e.*, the methyl group is attached to the benzene  
ring rather than to a nitrogen. When the crude product  
was chromatographed on nonalkaline Woelm alumina,  
a sharp-melting (200–201°) solid, characterized as the  
monomethyl derivative X, was isolated from the early  
eluates. The position of substitution has not yet been  
proved. However, the 4 (10) position (*i.e.*, “*ortho*”  
to nonfused N) should be favored by the ability of the  
metal to coordinate with an electron pair on the nitro-  
gen while the hydrogen in the adjacent position is re-  
moved by attack from the protophilic butyl anion.<sup>7</sup>

and G. F. Mower, *ibid.*, **80**, 2783 (1958); (b) J. R. Roland and B. C. Mc-  
Kusick, *ibid.*, **83**, 1652 (1961).

(7) H. Gilman and J. W. Morton, Jr., *Org. Reactions*, **8**, 261 (1954).

**Reactions at the Nitrogen Atoms.** When propylene was passed into a solution of I in concentrated sulfuric acid under the normal Friedel-Crafts conditions, little, if any, C-alkylated product was obtained; rather, a high yield of N-isopropyltetraazapentalenium hydrogen sulfate formed. The latter was isolated as the iodide XIa by neutralization of the reaction mixture and treatment with sodium iodide.

The N-methyl derivative XIb was prepared by prolonged treatment of I with methyl iodide, and more readily with methyl sulfate at 150°, followed by treatment of the resulting water-soluble methosulfate with aqueous sodium iodide.

The cationic derivatives are light-sensitive, crystalline solids. The yellow iodide XIb, when heated at reduced pressure, reverted to methyl iodide and I. The ultraviolet spectra of I, XIa, and XIb are shown in Table I.

**Table I.** Ultraviolet Absorption Maxima for Dibenzotetraazapentalene I and Its N-alkylated Derivatives XIa,b

I		XIa		XIb	
$\lambda_{\max}$ , m $\mu$	$\epsilon_{\max}$	$\lambda_{\max}$ , m $\mu$	$\epsilon_{\max}$	$\lambda_{\max}$ , m $\mu$	$\epsilon_{\max}$
402	38,300	378	19,700	377	20,000
382	23,300	362	19,200	361	19,900
364	7,740	323	10,100	323	10,400
323	4,110				
308	2,850				
255	63,300	241	32,900	239	35,000

The ultraviolet spectrum of the N-isopropyl cation XIa is almost identical with that of the N-methyl derivative XIb. The spectra of XIa and XIb are equally shifted toward shorter wavelengths with respect to the corresponding peaks in the spectrum of I.

**Complex Formation.** Dibenzotetraazapentalene functions as a moderately weak  $\pi$  base in the presence of strong  $\pi$  acids such as tetracyanoethylene and 7,7,8,8-tetracyanoquinodimethane (TCNQ).<sup>8</sup> The latter appears to form a more stable complex with I than does tetracyanoethylene. Treatment of TCNQ with compound I in warm acetonitrile gave dark green crystals of the 1:1  $\pi$  complex. The complex is diamagnetic and exhibits a resistivity of  $4.6 \times 10^8$  ohm cm. The solid gives green solutions when cold; however, the color is discharged on heating, indicating thermal dissociation. The complex is also dissociated in chloroform by differential solubility of its two components; the insoluble TCNQ separates, leaving the soluble compound I behind. Compound I thus appears to be only a moderately strong  $\pi$  base, which is not surprising in view of the presence of the four electronegative ring nitrogen atoms.

(8) (a) R. E. Merrifield and W. D. Phillips, *J. Am. Chem. Soc.*, **80**, 2778 (1958); (b) L. R. Melby, R. J. Harder, W. R. Hertler, W. Mahler, R. E. Benson, and W. E. Mochel, *ibid.*, **84**, 3374 (1962).

Silver salts and salts of copper(I) also react with compound I to form 2:1 complexes. The silver n complex was unaffected by recrystallization from methylformamide, while the cuprous cyanide complex was broken into its components on warming in a nitrile.

**Reactions with Ring Opening.** Although an acetic acid solution of I is stable to potassium permanganate, the molecule is readily attacked by peracetic acid under relatively mild conditions with cleavage of a N-N bond. When a chloroform solution of I was treated with peracetic acid, an oxidative cleavage occurred with the formation of 2-(*o*-nitrosophenyl)-2H-benzotriazole (XII). This cream-colored solid, mp 185–185.5° solves in organic solvents to yield green solutions, characteristic of nitroso compounds. The physical and spectral data suggest that the nitroso compound probably exists as the dimer in the solid state.

The structure of the product was substantiated by independent synthesis through peracetic acid oxidation of 2-(*o*-aminophenyl)-2H-benzotriazole (XIII)

A nonfused nitrogen with its relatively high electron density would be a favorable site of attack for electrophilic peracid. The accompanying electron shift leads directly to the corresponding nitrosophenylbenzotriazole XII.

Similarly, lithium aluminum hydride converted dibenzotetraazapentalene to 2-(*o*-aminophenyl)-2H-benzotriazole (XIII).<sup>3b</sup>

When the tetraaza derivative I was hydrogenated in acetic acid at 125° with 5% palladium on carbon, a colorless solid, mp 121–122°, which was identified as 2-(*o*-acetamidophenyl)-2H-4,5,6,7-tetrahydrobenzotriazole (XIV), was isolated. The identical substance was obtained from the catalytic hydrogenation<sup>9</sup> of I followed by acetylation.

An attempt to replace the halogen atom in the n-bromodibenzotetraazapentalene IIb with a methyl group by reaction with cuprous cyanide in refluxing N-methylpyrrolidone<sup>10</sup> resulted in N-N cleavage with formation of cyano-2-(*o*-aminophenyl)-2H-benzotriazole (XV) in 60% yield. XV was converted to the corresponding

(9) K. Fries, W. Franke, and W. Burns [*Ann.* **511**, 241 (1934)] reported that hydrogenation of 2-phenyl-2H-benzotriazole with BaSO<sub>4</sub> in acetic acid gave reduction of the fused six-membered ring leaving the 2-aryl group intact.

(10) M. Newman and H. Boden, *J. Org. Chem.*, **26**, 2525 (1961).

nido derivative XVI by hydrolysis with sulfuric

ation of XV and XVI as 5'-cyano- and 5'-nido-2'-aminophenyl-2H-benzotriazoles, respectively, was established through independent syn-

2-(*o*-Acetamidophenyl)-2H-benzotriazole was brominated in acetic acid to obtain the 5'-derivative XVIII. The position of the bromo-*para* to the acetamido group was confirmed by the proton nmr spectrum. Replacement of the halogen by cyano with cuprous cyanide and hydrolysis with dilute alkali or concentrated sulfuric acid gave the same cyano and carboxy derivatives, XV and XVI, respectively, as did the above described route.

Comparison of derivatives from both routes confirms: (a) the preferred position for halogenation (and nitration) in dibenzo-1,3a,4,6a-tetraazapentalene is at the 2 (or 8) position, *i.e.*, *para* to a non-nitrogen; (b) that the ring-opening reaction occurs *via* cleavage of the N-N bond in which the nitrogen is attached to the negatively substituted benzene ring.

In a similar manner, treatment of the dibromide IIb with cuprous cyanide produced the corresponding 5,5'-2-(2'-aminophenyl)-2H-benzotriazole (VIa), and mononitrotetraazapentalene IIc yielded the 5'-2-(5'-nitrophenyl)-2H-benzotriazole (XIX). Substituted pentalene I also underwent cleavage, at an appreciably slower rate, to form compound III. This ring-opening reaction did not occur with cuprous cyanide.

**Benzo-1,3a,4,6a-tetraazapentalenes.** It was of interest to determine the physical and chemical consequences of removing one of the benzo moieties from the hetero system. Two routes were found which lead to benzo-1,3a,4,6a-tetraazapentalene (XXI) and 5,6-tetramethylene-2,3-benzo derivative XXII, respectively.

XXI

XXII

Monobenzo-1,3a,4,6a-tetraazapentalene XXI was prepared by cyclization of 2-(*o*-nitrophenyl)-2H-triazole

(XXIII) with trimethyl phosphite.<sup>11</sup> Compound XXIII was prepared by treatment of 1,2,3-triazole with *o*-fluoronitrobenzene.

The resulting mixture of 1- and 2-arylated triazoles could be separated by distillation. The 1 isomer XXIV was identified by comparison with an authentic sample prepared by the addition of acetylene to *o*-nitrophenyl azide.<sup>11</sup>

Purification of the monobenzo-1,3a,4,6a-tetraazapentalene by vacuum distillation and recrystallization from ethanol gave colorless crystals, mp 108.8–109.7°, whose analysis was in agreement with the structure XXI (C<sub>8</sub>H<sub>6</sub>N<sub>4</sub>). The compound possessed a distinct quinoline-like odor.

A similar deoxygenative cyclization with *o*-nitrophenyl-1H-triazole (XXIV) gave the isomeric 2,3-benzo-1,3a,6,6a-tetraazapentalene.<sup>11</sup>

5,6-Tetramethylene-2,3-benzo-1,3a,4,6a-tetraazapentalene (XXII) was prepared by conversion of 2-(*o*-aminophenyl)-2H-tetrahydrobenzotriazole (XXV) to the corresponding azide XXVI followed by thermal decomposition, in a manner similar to that employed in the preparation of I.<sup>3</sup> From the concentrated reaction mixture was obtained the tetraazapentalene XXII as an almost colorless solid, mp 131.5–133°.

A comparison of the ultraviolet absorption spectra of the two monobenzo-1,3a,4,6a-tetraazapentalenes in Table II reveals their similarity.

The nonfluorescent XXI and XXII exhibit a pronounced hypsochromic shift in the ultraviolet spectra,

(11) J. C. Kauer and R. A. Carboni, *J. Am. Chem. Soc.*, **89**, 2633 (1967).

**Table II.** Ultraviolet Absorption Spectra of Monobenzotetraazapentalenes\* XXI and XXII

XXI		XXII	
$\lambda_{\max}$ , m $\mu$	$\epsilon_{\max}$	$\lambda_{\max}$ , m $\mu$	$\epsilon_{\max}$
343	21,800	351	28,200

236	27,700	242	25,900

\* Measured in ethyl alcohol.

compared to the dibenzo analog I. The long-wavelength region is without the prominent fine structure which characterizes compound I and its benzo-naphtho analogs.<sup>3</sup>

Both of the benzotetraazapentalenes XXI and XXII reacted with tetracyanoethylene (TCNE) in tetrahydrofuran solution to form a deep blue complex. In the case of XXI, however, the solution liberated hydrogen cyanide slowly, and the blue color was replaced with a deep reddish purple. These transformations were much more rapid in *N,N*-dimethylformamide. The deeply colored tricyanovinyl derivative XXVII precipitated on dilution of the solution with water.

The monobenzotetraazapentalene reacted much more rapidly with methyl iodide than did the dibenzo derivative I. The resulting stable methiodide XXVIII exhibited an ultraviolet spectrum in water solution very similar to that of the pentalene XXI in hydrochloric acid, suggesting that the positions of methylation and alkylation are the same.

## Experimental Section

**Monobromodibenzotetraazapentalene (IIb).** a. **From Bromination of I.** A solution of 20.8 g (0.10 mole) of dibenzo-1,3a,4,6a-tetraazapentalene (I) in 2 l. of refluxing acetonitrile was stirred vigorously while 17.8 g (0.10 mole) of *N*-bromosuccinimide in 250 ml of acetonitrile was added dropwise over a period of 20 min. The clear yellow solution was refluxed for 2.5 hr, during which time a yellow solid (dibromo derivative) precipitated. The latter was removed from the hot mixture by filtration. The filtrate was concentrated to two-thirds of its original volume, then filtered while hot to remove a small quantity of solid. The acetonitrile solution was cooled to 5° to give 20 g (70%) of product, mp 196–198°. Successive recrystallizations from benzene and hexane gave an analytical sample, mp 201.0–202.5°.

*Anal.* Calcd for  $C_{12}H_8N_4Br$ : C, 50.19; H, 2.46; N, 19.51; Br, 27.83. Found: C, 50.26; H, 2.47; N, 19.39; Br, 27.66.

b. **From Thermolysis of 2-(5'-Bromo-2'-azidophenyl)-2H-benzotriazole (V).** A solution of 3.4 g of V in 30 ml of *o*-dichlorobenzene was heated at 180° for 1 hr, during which time nitrogen evolved and the solution turned yellow-brown. The solution was concentrated to one-third volume and cooled. The yellow crystalline solid (2.4 g) was collected by filtration, washed with fresh solvent, and dried, mp 205–206°. The infrared spectrum of this material was identical with that of the product from method a.

**Dibromodibenzo-1,3a,4,6a-tetraazapentalene (IIIb).** a. A warm, stirred mixture of I (1.0 g, 0.005 mole) and 85 ml of glacial acetic acid (50°) was treated with 2 g (0.0125 mole) of bromine in acetic acid. A bright yellow precipitate formed almost immediately. The mixture was heated at 70° for 15 min, cooled to 50°, and filtered. The first crop of crystals (1.4 g) was recrystallized from *o*-dichlorobenzene to obtain bright yellow crystals, mp 295–297°.

*Anal.* Calcd for  $C_{12}H_8Br_2N_4$ : C, 39.38; H, 1.65; N, 15.31; Br, 43.67. Found: C, 39.15; H, 1.60; N, 15.15; Br, 43.20.

The ultraviolet spectrum (in chloroform) exhibited the characteristic three areas of absorption, the strongest peaks in each group being 424 m $\mu$  ( $\epsilon$  52,000), 314 (3660), and 268 (75,760).

b. **Bromination of IIb.** A solution of 2.87 g (0.01 mole) of IIb in chloroform was treated with 1.6 g (0.01 mole) of bromine in chloroform, giving an immediate yellow product (3.2 g) which exhibited the same infrared spectrum and melting point as the dibromo derivative above.

**Dichlorodibenzo-1,3a,4,6a-tetraazapentalene (IIIa).** Compound I (1.0 g, 0.005 mole) was added to a stirred solution of 0.8 g (0.11 mole) of chlorine in 34 ml of glacial acetic acid. The mixture was gradually heated to reflux, and approximately half of the solvent was removed by distillation. The cooled concentrate was diluted with three volumes of water, and the insoluble precipitate was collected by filtration (1.0 g). Two recrystallizations of the dried solid from *o*-dichlorobenzene gave yellow, fanlike crystals, mp 303–304°.

*Anal.* Calcd for  $C_{12}H_8N_4Cl_2$ : C, 52.01; H, 2.19; Cl, 25.99. Found: C, 51.85; H, 2.48; Cl, 25.65.

**Nitration of Dibenzo-1,3a,4,6a-tetraazapentalene. Mononitration (IIc).** To 700 ml of cold (10°) 25% nitric acid was added with stirring 50 g of I. The yellow suspension was stirred vigorously while warming to room temperature during 1.5 hr. After standing overnight at 25°, an orange solid was collected by filtration, washed with water, and dried. The crude mononitro derivative (11 g, 91%) was purified by chloroform extraction, mp 301–303°.

*Anal.* Calcd for  $C_{12}H_7N_5O_2$ : C, 56.91; H, 2.79; N, 27.66. Found: C, 57.21; H, 3.00; N, 27.92.

**Dinitration (IIId).** Compound I (1.0 g) was added in small portions to 15 ml of concentrated nitric acid at 5° with stirring. The mixture was stirred for an additional 30 min, then poured into ice-water. A quantitative yield of the yellow-orange dinitro compound, mp 340° dec, was obtained. *Anal.* Calcd for  $C_{12}H_6N_6O_4$ : C, 48.33; H, 2.03; N, 28.18. Found: C, 48.21; H, 2.25; N, 28.08.

**Tetranitration (IIIf).** To a stirred solution of 1 g of I in concentrated  $H_2SO_4$  was added an excess (20 ml) of fuming red nitric acid with slight cooling. After 15 min, the mixture was heated to 60° and maintained at this temperature for an additional 15 min. The orange mixture was cooled somewhat and poured into five volumes of ice-water. The orange tetranitro derivative was collected by filtration (1.55 g). Recrystallization from dimethylformamide yielded an orange-red solid, mp 410° dec, which contained one solvent molecule of crystallization.

*Anal.* Calcd for  $C_{12}H_4N_8O_8$ : C, 39.05; H, 2.40; N, 27.33. Found: C, 39.47; H, 1.65; N, 27.82.

Dilute solutions of each of the nitro compounds in organic solvents such as acetone, tetrahydrofuran, or dimethylformamide exhibited a strong greenish fluorescence.

**Monoaminodibenzo-1,3a,4,6a-tetraazapentalene (IIId).** A slurry of 10 g of the nitro compound IIc and 10% palladium-on-carbon catalyst (0.5 g) in 150 ml of *N,N*-dimethylformamide was hydrogenated at 30–40 psi of hydrogen for 1 hr. Most of the hydrogen was absorbed during the first 10 min. The yellow-green slurry was heated to boiling and filtered under nitrogen. On cooling, a crop (5.4 g) of coppery crystals separated. An additional 2.3 g of product was obtained from the concentrated filtrate. The crude product was purified by continuous extraction with chloroform. An analytical sample was prepared by sublimation at 250° (1 mm). The light yellow needles darkened in air at 240° and melted slowly when placed in a bath at 318°.

*Anal.* Calcd for  $C_{12}H_9N_5$ : C, 64.56; H, 4.07; N, 31.38. Found: C, 64.35; H, 3.89; N, 31.13.

**Acetamide derivative,** recrystallized from acetonitrile, had mp 334°,  $\lambda_{\max}^{H_2O}$  420 m $\mu$  ( $\epsilon$  42,800), 397 (24,700), 378 (8650), 324 (2100), 311 (4200), and 264 (55,600).

*Anal.* Calcd for  $C_{11}H_{11}ON_5$ : C, 63.39; H, 4.18; N, 26.40. Found: C, 63.78; H, 4.45; N, 26.37.

**Benzamide derivative,** yellow needles from acetonitrile, had mp 278–280°.

*Anal.* Calcd for  $C_{11}H_{10}ON_5$ : C, 69.73; H, 4.01; N, 21.40. Found: C, 69.97; H, 4.17; N, 21.03.

**Diaminodibenzo-1,3a,4,6a-tetraazapentalene (IIId).** The dinitro derivative (5.0 g, IIId) was hydrogenated as described above. The solid (2.8 g) which separated from the dimethylformamide solution was purified by successive extractions with 20 ml of hot *N,N*-dimethylformamide and four 25-ml portions of dimethyl sulfoxide. Dilution of the combined extracts with methanol gave 1.6 g (40%) of the diamino derivative. An additional 1.1 g of crude product was recovered from the original reaction solution by dilu-

water. An analytical sample was prepared by recrystallization from dimethyl sulfoxide. The maroon needles melted at ca. 265°.

Calcd for  $C_{12}H_{10}N_4$ : C, 60.49; H, 4.24; N, 35.28. Found: C, 60.24; H, 4.24; N, 35.00.

**amide derivative**, maroon crystals, had mp 380° dec.

Calcd for  $C_{12}H_{10}N_4O_2$ : C, 69.94; H, 4.08; N, 18.82. Found: C, 69.57; H, 3.96; N, 18.92.

**benzo-1,3a,4,6a-tetraazapentalene-2',8'-disulfonyl Chloride**  
A solution of 25 g of dibenzo-1,3a,4,6a-tetraazapentalene in of chlorosulfonic acid was stirred, and the temperature was raised to 90° over a period of 3 hr. The solution was heated for 10°. It was then cautiously poured onto ice (behind shields in hood). The solid was separated by filtration and was fully washed with water and then air-dried. The crude yellow solid weighed 49 g. A 36-g portion was extracted with of boiling ethyl acetate. After cooling, the undissolved sulfonyl chloride (13.8 g) was separated by filtration. The filtrate was evaporated, and the residue was extracted with of ethyl acetate at room temperature. The undissolved sulfonyl chloride (3.9 g) was combined with the 13.8-g residue and recrystallized from methylene chloride-hexane to give golden yellow platelets melting at 268–269.5° dec;  $\lambda_{max}$  (ε 45,700), 350 (2140), 333 (2350), 283 (54,600), and 238 (54,700).

Calcd for  $C_{12}H_8N_4S_2O_4Cl_2$ : C, 35.58; H, 1.49; N, 13.83; S, 17.05. Found: C, 36.06; H, 1.58; N, 13.64; Cl, 17.05.

Processing the residues, an over-all yield of 51% of this sulfonyl chloride could be obtained. The disulfonyl chloride is resistant to hydrolysis in neutral solution (e.g., boiling acetone) but reacted with ammonia and amines to form amides.

**N,N',N'',N'''-Tetramethyldibenzo-1,3a,4,6a-tetraazapentalenedi-imide**, from dimethylamine and IIIc in methylene chloride, gave bright yellow crystals, mp 318–320°, when recrystallized from methylene chloride-hexane.

Calcd for  $C_{14}H_{12}N_4O_2$ : C, 45.50; H, 4.30; N, 19.90. Found: C, 45.45; H, 4.40; N, 19.60.

**azido-1,3a,4,6a-tetraazapentalene**. To a hot, solution (135°) of tetranitrodibenzo-1,3a,4,6a-tetraazapentalene, 10 g) in 400 ml of dimethylformamide was added 10 g of sodium azide in 80 ml of dimethylformamide. The mixture was stirred in color. The reaction mixture was kept at 80–85°, then cooled in an ice bath. The yellow-orange crystals separated were collected by filtration and washed with ethyl ether. The yield was 8.4 g. A sample melted with decomposition when placed in a bath at 200°. *Anal.* Calcd for  $C_{12}H_8N_{10}O_4$ : C, 37.90; H, 1.06; N, 44.21. Found: C, 37.90; H, 1.06; N, 44.00.

Infrared absorption of the compound exhibited the characteristic azide band at 4.75  $\mu$  and the nitro bands in the 6.5–7.5- $\mu$  region.

**2-Nitrosophenyl-2H-benzotriazole (XII)**. *a.* From I and c. *Acid*. A mixture of 8.3 g (0.04 mole) of the tetraazapentalene I in 120 ml of chloroform and 20 ml of 40% peracetic acid in 16 ml of glacial acetic acid was heated on a steam bath for 2 hr. The mixture was cooled and poured into a cold solution of 50 g of sodium hydroxide. The organic layer was removed and evaporated to dryness. The solid residue was removed from chloroform to yield crystals melting at 191–192°. The total yield was 7.2 g (75%). The infrared spectrum of the product showed a strong band at 7.87  $\mu$  characteristic of nitroso group.

The ultraviolet spectrum in ethanol showed a weak maximum at 740 m $\mu$  (ε 45) as well as strong absorption at 284 m $\mu$  (ε 22,600) and 227 m $\mu$  (ε 22,600).

**From 2-(o-Aminophenyl)-2H-benzotriazole (XIII) and Peracetic Acid**. 2-(o-Aminophenyl)-2,1,3-benzotriazole (XIII) (8.3 g, 0.04 mole) in 100 ml of chloroform was treated with 12 ml of 40% peracetic acid in a manner similar to that described above. There was obtained a total of 7.3 g of pale yellow product, mp 185–186°. The infrared spectrum was identical with that of the nitroso compound XII obtained from the tetraazapentalene I.

Calcd for  $C_{12}H_8N_4O$ : C, 64.28; H, 3.60; N, 24.99; (monomer), 224. Found: C, 63.96; H, 3.72; N, 24.56; (in ethylene chloride), 229.

**Complex Formation with Dibenzo-1,3a,4,6a-tetraazapentalene (I)**. *a.* With Silver Nitrate. To a solution of 1.0 g of I in 75 ml of warm tetrahydrofuran was added a solution of silver nitrate (2 g) in acetone. A yellow solid formed immediately. The mixture was stirred for 3 hr, filtered, and washed with fresh acetonitrile and

chloroform (1.7 g). Recrystallization from dimethylformamide yielded a crop of yellow crystals, mp >300°.

*Anal.* Calcd for  $[C_{12}H_8N_4 \cdot 2AgNO_3]$ : C, 26.30; H, 1.47; N, 15.34. Found: C, 26.66; H, 1.44; N, 15.62.

*b.* With Tetracyanoquinodimethane (TCNQ). A solution of 0.4 g (0.02 mole) of TCNQ in hot acetonitrile (25 ml) was mixed with 0.41 g (0.02 mole) of the tetraazapentalene I in 25 ml of hot acetonitrile. The resulting yellow-green solution was heated at reflux for 5 min and allowed to cool slowly. A crop of dark green crystals (0.52 g) separated. *Anal.* Calcd for  $C_{12}H_8N_6$  (1:1 complex): C, 69.89; H, 2.94; N, 27.17. Found: C, 69.90; H, 3.51; N, 27.80.

The complex is diamagnetic and exhibits a resistivity of  $4.6 \times 10^8$  ohm cm. The product is decomposed to starting materials by differential solubility (in chloroform).

*c.* With Cuprous Cyanide. Compound I (2.08 g, 0.01 mole) and cuprous cyanide (0.89 g, 0.005 mole—as  $[CuCN]_2$ ) were each dissolved in 25 ml of warm N-methylpyrrolidone, mixed, and heated on a steam bath for 30 min. The reaction mixture was filtered and the filtrate was evaporated to dryness. The residue was triturated in benzene, collected by filtration, and then dried. The light yellow-green solid (1.72 g, 89% yield) melted at 277–278° dec.

*Anal.* Calcd for  $C_{12}H_8N_4Cu_2$  (1:1 complex): C, 43.42; H, 2.09; N, 21.70. Found: C, 41.14; H, 2.22; N, 20.88.

The infrared spectrum showed an absorption band at 4.65  $\mu$  ( $CuCN$ ) and all the bands of I except that at 8.0  $\mu$ .

**Reaction with n-Butyllithium**. Compound I (6.5 g, 0.025 mole) in 250 ml of benzene was treated with a hexane solution of n-butyllithium (0.06 mole) at room temperature with stirring for 1 hr. The mixture was refluxed for 2 hr and treated with 0.07 mole of methyl iodide. After an additional hour of heating, the mixture was cooled and treated with water. The dried benzene layer was evaporated to dryness to yield a yellow solid residue (5.4 g). Portions of the product were recrystallized from various solvents including ethanol, benzene, and cyclohexane. The bright yellow crystals analyzed correctly for a monomethyl derivative X despite a broad melting point range, suggesting an isomeric mixture.

*Anal.* Calcd for  $C_{13}H_{10}N_4$ : C, 70.25; H, 4.54; N, 25.21. Found: C, 70.26; H, 4.91; N, 24.99.

The infrared and ultraviolet spectra of the methyl derivative are very similar to those of the parent compound, indicating that the electronic system has been little altered, i.e., the methyl group is attached to the benzene ring rather than to a nitrogen. The solid was chromatographed on nonalkaline Woelm alumina with benzene, benzene-methylene chloride, and finally ethyl acetate. A small quantity of sharp-melting (200–201°) product (X) was isolated from the initial eluates;  $\lambda_{max}$  405 m $\mu$  (ε 44,400), 385 (24,400), 367 (7810), 324 (4620) m $\mu$ , 313 (2640), 310 (2975), 303 (2264), 296 (2240), and 259 (60,825).

**N-Alkylations of I**. *a.* **Dibenzo-1-isopropyl-1,3a,4,6a-tetraazapentalenium Iodide (XIa)**. A solution of I (10 g, 0.048 mole) in 50 ml of concentrated sulfuric acid was stirred while propylene was passed in during a 20-min period. The reaction mixture was cooled with an ice bath during this period, and the reaction flask was provided with a Dry Ice-acetone condenser to prevent loss of propylene. The mixture was allowed to come to room temperature slowly, and the mixture was poured onto 800 g of ice. After a small amount of waxy material was removed by filtration, the pH of the mixture was adjusted to 8 with sodium carbonate, and the clear yellow solution was allowed to stand at room temperature for 3 days. Excess saturated aqueous sodium iodide solution was added, giving an immediate bright-yellow precipitate. The latter was collected by filtration, washed with water, and dried *in vacuo* at room temperature. The product XIa (16 g, 88%) melted with decomposition at 140° after recrystallization from methylene chloride. *Anal.* Calcd for  $C_{13}H_{11}N_4I$ : C, 47.63; H, 4.00; N, 14.81; I, 33.55. Found: C, 47.92; H, 4.16; N, 14.93; I, 34.22.

*b.* **Dibenzo-1-methyl-1,3a,4,6a-tetraazapentalenium Iodide (XIb)**. A mixture of 5 g (0.024 mole) of I and 200 ml of methyl iodide was heated at reflux for 1 week. The orange crystals (2 g, 24%) which separated were collected by filtration and air dried, mp 191° dec (to blue melt).

*Anal.* Calcd for  $C_{13}H_{11}N_4I$ : C, 44.59; H, 3.17; N, 16.00; I, 36.24. Found: C, 45.00; H, 3.53; N, 15.60; I, 36.01.

*c.* **Dibenzo-1-methyl-1,3a,4,6a-tetraazapentalenium Methosulfate**. A mixture of 15 g (0.072 mole) of I and 140 ml of freshly distilled dimethyl sulfate was heated at 150° for 45 min, cooled, and treated with 1 l. of ether containing 80 ml of methylene chloride. The ether solution was separated by decantation, and the insoluble oil was further extracted with a mixture comprising 400 ml of

methylene chloride and 400 ml of acetone, whereupon the oil changed to a light-tan solid (18.3 g). The latter was recrystallized from a methanol-acetone-ether mixture, yielding nearly colorless crystals of the methosulfate, mp 199° dec.

*Anal.* Calcd for  $C_{11}H_{11}N_4O_2S$ : N, 16.76; S, 9.59. Found: N, 16.51; S, 9.71.

**2-(*o*-Aminophenyl)-2H-4,5,6,7-tetrahydrobenzotriazole (XXV).** A solution of 1.3 g of 2-(*o*-aminophenyl)-2H-benzotriazole (XIII) in 25 ml of acetic acid was hydrogenated at 40 psi using 100 mg of 10% palladium-on-charcoal catalyst. The solution was filtered, and solvent was removed under vacuum. An ethereal solution of the residue was washed with dilute sodium carbonate solution. Evaporation of the organic layer yielded colorless crystals of the tetrahydro derivative (XXV) (85% yield) which, after recrystallization from petroleum ether, melted at 78–80°;  $\lambda_{\text{max}}^{\text{EtOH}}$  320 m $\mu$  ( $\epsilon$  7200), 269 (9610), and 238 (20,500).

*Anal.* Calcd for  $C_{12}H_{11}N_4$ : C, 67.26; H, 6.59; N, 26.15. Found: C, 67.43; H, 6.51; N, 26.06.

**N-Acetyl derivative XIV**, mp 121–122°, was identical with the product formed when the tetraazapentalene I was hydrogenated in acetic acid at 125° with 5% palladium-on-carbon and a hydrogen pressure of 1000 psi.

**2-(*o*-Azidophenyl)-5,6,7,8-tetrahydrobenzotriazole (XXVI).** Compound XXV (10.3 g, 0.05 mole) in 40 ml of concentrated hydrochloric acid and 50 ml of water was diazotized at 5° with a solution of sodium nitrite (3.7 g, 0.05 mole) which was added dropwise. The mixture was stirred for an additional 90 min and filtered to remove a small amount of undissolved solid. The cold, stirred filtrate was treated dropwise with an aqueous solution of sodium azide (3.3 g, 0.05 mole). A gummy solid separated, and nitrogen was evolved. The reaction mixture was stirred rapidly at 5° for 90 min, during which time the product was transformed to a grainy, light yellow solid (6.3 g). The azide melted at 48.5–49.6° after recrystallization from pentane.

*Anal.* Calcd for  $C_{12}H_{12}N_4$ : C, 59.98; H, 5.03; N, 34.98. Found: C, 60.49; H, 4.96; N, 35.27.

**5,6-Tetramethylene-2,3-benzo-1,3a,4,6a-tetraazapentalene (XXII).** A solution of 10.3 g of crude azide XXVI in 200 ml of decalin was heated at reflux for 1 hr, during which time 1 mole of nitrogen was evolved. Most of the decalin was removed by distillation at atmospheric pressure. On cooling, the concentrated solution set to a brownish yellow crystalline mass. The solid was collected by filtration and recrystallized from hexane. A crop of yellow non-fluorescent crystals (mp 131.5–133°, 4.35 g) was obtained. An additional 0.9 g of product was isolated from the concentrated mother liquor;  $\lambda_{\text{max}}^{\text{EtOH}}$  351 m $\mu$  ( $\epsilon$  28,200), 278 (2850), and 242 (25,900).

*Anal.* Calcd for  $C_{12}H_{12}N_4$ : C, 67.90; H, 5.70; N, 26.40. Found: C, 68.32; H, 5.94; N, 26.25.

**2-(*o*-Nitrophenyl)-2H-triazole (XXIII).** A mixture of 6.9 g of 1,2,3-triazole, 14.1 g of *o*-fluoronitrobenzene, and 10.6 g of sodium carbonate (anhydrous) in 45 ml of *N,N*-dimethylformamide was heated to reflux for 65 hr. The product was poured onto ice and extracted with ether. The ether extract was dried with magnesium sulfate, and solvent was removed under reduced pressure. The residue was distilled (oil bath) through a Vigreux column to yield 11.6 g (62%) of 2-(*o*-nitrophenyl)-2H-triazole, bp 97–99° (40  $\mu$ ). The pot residue was nearly pure 1-(*o*-nitrophenyl)-1H-triazole (XXIV, 20%) which was also prepared by the reaction of acetylene with *o*-nitrophenyl azide.<sup>11</sup> The 2H-triazole XXIII was recrystallized from pentane-benzene (5:3) at –20° to obtain colorless crystals, mp 27.0–27.5°.

*Anal.* Calcd for  $C_8H_6N_4O_2$ : C, 50.53; H, 3.18; N, 29.47. Found: C, 50.87; H, 3.30; N, 29.66.

**2,3-Benzo-1,3a,4,6a-tetraazapentalene (XXI).** A solution of 10.5 g (0.05 mole) of 2-(*o*-nitrophenyl)-2H-triazole (XXIII) and 25 g of triethyl phosphite in 25 ml of xylene was heated for 6 hr in an oil bath maintained at 150°. The product was vacuum distilled, and 6.81 g of crude 2,3-benzo-1,3a,4,6a-tetraazapentalene (XXI) was collected at 100° (50  $\mu$ ). The distillate solidified and was recrystallized from ethanol to yield 5.5 g (70%) of colorless crystals which melted at 107–108°. A sample recrystallized three times from ethanol melted at 108.8–109.7°;  $\nu_{\text{max}}$  (KBr) 3150 m, 3110 m, 1515, 1472 m, 1460, 1370 vs, 1349, 1270, 1210, 1168, 1097, 995 m, 920 vs, 890 m, 792 m, 746 vs, 731 vs, 703 m, and 688 vs  $\text{cm}^{-1}$ ;  $\lambda_{\text{max}}^{\text{EtOH}}$  311 m $\mu$  ( $\epsilon$  14000), 267 (5450), 238 (9390), and 222 (14970).

*Anal.* Calcd for  $C_8H_6N_4$ : C, 60.75; H, 3.82; N, 35.42. Found: C, 60.67; H, 4.22; N, 35.19.

**6-( $\alpha,\beta$ -Tricyanovinyl)-2,3-benzo-1,3a,4,6a-tetraazapentalene (XXVII).** A solution of 0.84 g of XXI (0.0053 mole) in 5 ml of *N,N*-dimethylformamide (DMF) was treated with a solution of 0.70

g of tetracyanoethylene in 10 ml of DMF. The initial green of the solution gradually turned to deep red. The solution warmed on the steam bath for 30 min and was poured over of ice. The solid product was separated by filtration, water washed, and dried under a nitrogen stream (0.85 g). The deep red crystals of tricyanovinyl derivative XXVI melted at 264–after recrystallization (with some difficulty) from a mixture of benzene and 100 ml of hexane;  $\lambda_{\text{max}}^{\text{EtOH}}$  505 m $\mu$  ( $\epsilon$  2383 (6300), 322 (12,100), 308 (9750), and 231 (16,620).

*Anal.* Calcd for  $C_{11}H_5N_7$ : C, 60.23; H, 1.94. Found: 61.00; H, 2.06.

**N-Methyl-2,3-benzo-1,3a,4,6a-tetraazapentalenium (XXVIII).** A solution of 0.30 g of 2,3-benzo-1,3a,4,6a-tetrapentalene in 10 ml of methyl iodide was sealed in a glass tube heated at 100° for 20 hr. The tube was cooled and opened; the solid product was separated by filtration and washed with carbon tetrachloride. The yellow, crystalline, water-soluble product XXVIII melted at 193.6–194° dec;  $\lambda_{\text{max}}^{\text{EtOH}}$  318 m $\mu$  ( $\epsilon$  1268 (4560), and 225 (33,300).

*Anal.* Calcd for  $C_8H_7N_4I$ : C, 36.02; H, 3.02; N, 18.90. Found: C, 36.04; H, 3.02; N, 18.90.

**Reactions of Dibenzotetraazapentalene Derivatives with Cyano-**

**a. 2-(2'-Amino-5'-nitrophenyl)-2H-benzotriazole from IIc.** A mixture of IIc (5.0 g, 0.02 mole), 1.8 g (0.02 mole) of cuprous cyanide, and 20 ml of *N*-methylpyrrolidone was under reflux for 2 hr and poured into a mixture of 10 ml of ethylamine and 50 ml of water. The solid was collected by filtration, washed with water, then methanol, and finally dried (6.4 g). The solid was continuously extracted with benzene in a Soxhlet apparatus for 12 hr. From the evaporated benzene extract the obtained 2.3 g (46%) of XIX. An analytical sample, purified by benzene recrystallization and sublimation, melted at 251°;  $\lambda_{\text{max}}^{\text{EtOH}}$  350 m $\mu$  ( $\epsilon$  20,900), 295 (19,100), and 235 (16,600).

*Anal.* Calcd for  $C_{12}H_8N_6O_2$ : C, 56.47; H, 3.55; N, 36.02. Found: C, 55.61; H, 3.58; N, 37.26.

**b. 2-(2'-Amino-5'-cyanophenyl)-2H-benzotriazole (XV) from IIb.** A mixture of 2.87 g (0.01 mole) of IIb, 1.6 g (0.009 mole) of cuprous cyanide, and 20 ml of *N*-methylpyrrolidone was heated at reflux for 4 hr and poured into a dilute hydrochloric acid solution containing 5 g of ferric chloride. The mixture was warmed on a steam bath for 15 min and then cooled, and the solid was collected by filtration. The solid was triturated with methanol and dried (1.5 g (63% yield)). The solid, whose infrared spectrum was consistent with the structure of XV, was isolated. Two benzene recrystallizations yielded colorless crystals, mp 232–234°;  $\lambda_{\text{max}}^{\text{EtOH}}$  362 m $\mu$  ( $\epsilon$  13,500), 300 (12,76 (36,100), and 233 (28,300).

*Anal.* Calcd for  $C_{12}H_8N_4$ : C, 66.37; H, 3.86; N, 29.77. Found: C, 66.78; H, 3.91; N, 30.39.

Compound XV was prepared by an independent route: a mixture of 2-(2'-acetamido-5'-bromophenyl)-2H-triazole (2.5 g) (XVIII) (see below) with cuprous cyanide (2.0 ml of *N*-methylpyrrolidone). The reaction mixture was poured into an ethylenediamine-water mixture (10:100, v/v). The solid (1.42 g) was collected by filtration and recrystallized from methanol to yield 1.2 g (45%) of XV, mp 210–213°.

Hydrolysis of the 2-(2'-acetamido-5'-cyanophenyl)-2H-triazole (XX) with 1 equiv of sodium hydroxide (2 *N* solution) in the amine XV, which was identical with the product obtained from IIb.

**c. 2-(2'-Amino-5'-carboxamidophenyl)-2H-benzotriazole (VIa).** A mixture of XV or XX with sulfuric acid was heated at reflux for 30 min, then poured onto ice; mp 282–284.5° from acetone.

*Anal.* Calcd for  $C_{11}H_{11}ON_4$ : C, 61.65; H, 4.38; N, 27.60. Found: C, 61.85; H, 4.20; N, 27.60.

**d. 2-(2'-Aminophenyl)-5',5'- (or 4-) -dicyano-2H-benzotriazole (VIa) from IIb.** A mixture of IIb (3.7 g, 0.01 mole), 2.7 g (0.02 mole) of cuprous cyanide, and 20 ml of *N*-methylpyrrolidone was under reflux for 2 hr, then poured into a mixture of 50 g of ethylenediamine and 300 ml of water. The solid was collected by filtration, washed thoroughly with water, then extracted repeatedly with hot benzene. Evaporation yielded 1.2 g (45%) of product. Two recrystallizations from toluene-hexane yielded a yellow crystalline solid VIa, mp 244–246°;  $\lambda_{\text{max}}^{\text{EtOH}}$  381 m $\mu$  ( $\epsilon$  13,600), 280 (22,000), and 247 (28,100).

*Anal.* Calcd for  $C_{14}H_8N_6$ : C, 64.61; H, 3.09; N, 32.30. Found: C, 64.64; H, 3.00; N, 31.95.

**2-(2'-Acetamido-5'-bromophenyl)-2H-benzotriazole (XVIII)** a stirred solution of 84 g (0.357 mole) of 2-(*o*-acetamidophenyl-

ole (XVII) in 1.2 l. of glacial acetic acid containing 2 iv of fused sodium acetate was added 112 g (0.70 mole) e. The mixture was stirred at 50° for 3 hr, cooled, and th water. Crude XVIII was obtained in 90% yield. stallizations from methanol yielded a colorless product,

mp 179.5–180°;  $\lambda_{\text{max}}^{\text{EtOH}}$  320 (sh)  $\text{m}\mu$  ( $\epsilon$  11,100), 299 (16,450), 265 (17,800), 257 (sh) (16,200), and 299 (29,000).

Anal. Calcd for  $\text{C}_{14}\text{H}_{11}\text{BrN}_4\text{O}$ : C, 50.78; H, 3.35; N, 16.92: Found: C, 50.64; H, 3.39; N, 17.21.

The proton nmr spectrum is in accord with structure XVIII.

## Aromatic Azapentalenes. III. 1,3a,6,6a-Tetraazapentalenes

J. C. Kauer and R. A. Carboni

Contribution No. 1170 from the Central Research Department, Experimental Station, E. I. du Pont de Nemours and Company, Wilmington, Delaware.

Received November 17, 1966

**Abstract:** Syntheses of mono- and dibenzo-1,3a,6,6a-tetraazapentalene derivatives are described. A new ring-closure reaction leading to these as well as to the isomeric 1,3a,4,6a-tetraazapentalenes is based on the trialkyl phosphite deoxygenation of *o*-nitrophenyltriazole derivatives.

ous papers in this series have described the aration of several new aromatic azapenta- systems: dibenzo-1,3a,4,6a-tetraazapentalene, 3-benzo-1,3a,4,6a-tetraazapentalene (II),<sup>1</sup> and 1,3a,6,6a-tetraazapentalene (III).<sup>2</sup> This paper the preparation and chemical properties of and dibenzo-1,3a,6,6a-tetraazapentalenes and ivatives.

etic Routes to 1,3a,6,6a-Tetraazapentalenes. hesis of III by the pyrolysis of 1-(*o*-azidophenyl)-otriazole has been previously reported.<sup>2</sup> s of 1-(*o*-azidophenyl)-1H-triazole in a similar led to the monobenzo-1,3a,6,6a-tetraazapenta- in 44% yield. The cyclization is probably ef- y interaction of the 2p electrons of the center of the triazole ring with the developing nitrene

during pyrolysis. The precursory nitrophenyltriazole V was prepared *via* reaction of *o*-azidonitrobenzene with acetylene. Catalytic reduction of V gave the corresponding amine VI, which was converted to azide VII by diazotization and treatment with azide ion.

Benzo-1,3a,6,6a-tetraazapentalene (IV) is a colorless, nearly odorless solid with a dipole moment of 4.73 D. at 25° in benzene. Like the dibenzo derivative III, IV exhibits three main regions of absorption in the ultraviolet (Table I).

Table I. Ultraviolet Absorption Maxima for 1,3a,6,6a-Tetraazapentalenes

III		IV		II		XVII	
$\lambda_{\text{max}}$ , $\text{m}\mu$	$\epsilon_{\text{max}}$	$\lambda_{\text{max}}$ , $\text{m}\mu$	$\epsilon_{\text{max}}$	$\lambda_{\text{max}}$ , $\text{m}\mu$	$\epsilon_{\text{max}}$	$\lambda_{\text{max}}$ , $\text{m}\mu$	$\epsilon_{\text{max}}$
356	39,800	335	16,100	343	21,800	343	16,400
343	32,500	326	15,200			335	16,600
280	8,250	293	4,110	278	3,040	299	4,080
271	5,900	285	3,760			290	3,440
234	35,000	232	28,600	236	27,700	236	29,800

The ultraviolet absorption peaks of the isomeric benzo-1,3a,4,6a-tetraazapentalene II are included in the table for comparison.<sup>3</sup> It will be noted that the long-wavelength absorption of II is more intense and is hypsochromically shifted with respect to the corresponding absorption in IV. A similar effect has been noted in the dibenzo analogs I and III. The origins of these differences will be discussed in a subsequent communication.<sup>4</sup>

Several alternative procedures for generating these tetraazapentalenes directly from the more accessible nitro compounds were examined. An unsuccessful attempt was made to effect a deoxygenative ring closure of 1-(*o*-nitrophenyl)-1H-benzotriazole (VIII) to III by pyrolysis with ferric oxalate.<sup>5,6</sup> However, deoxygena-

(6) R. A. Abramovitch and K. A. H. Adams, *Can. J. Chem.*, **39**, 2516 (1961). These authors reported the successful ring closure of 2-(*o*-nitrophenyl)pyridine to pyrido[1,2-*b*]indazole.

tive cyclization of this triazole with phosphites and phosphines proceeded smoothly.<sup>7</sup> When VIII was heated with excess triethyl phosphite in xylene, tetraazapentalene III was isolated from the cooled solution in good yield and high purity. The by-products appeared to be very soluble in aromatic hydrocarbon solvents, facilitating the isolation of III. The *o*-nitrophenyltriazoles IX and X likewise gave the corresponding tetraazapentalenes in fair to good yields.

This reaction is importantly affected by the nature of the phosphorus compound. For instance, the reaction of VIII or IX with tributylphosphine is more rapid than with the less nucleophilic triethyl phosphite. The yields and product purities are much higher with the latter reagent, however. When the phosphine was employed with the ester X, attack at both the carbonyl oxygen atom and the nitro group occurred. The resulting product has been tentatively assigned the triazolo-quinoxaline structure XII.

Several intermediates are possible for these reactions. A univalent nitrogen species XIV may form by removal of oxygen atoms from the nitro groups. A prior for-

(7) The generation of nitrene-like intermediates in the phosphite deoxygenation of nitro compounds has been discovered independently in other laboratories: (a) J. I. G. Cadogan and M. Cameron-Wood, *Proc. Chem. Soc.*, 361 (1962); (b) J. I. G. Cadogan, M. Cameron-Wood, R. K. Mackie, and R. J. G. Searle, *J. Chem. Soc.*, 4831 (1965); (c) B. M. Lynch and Y.-Y. Hung, *J. Heterocyclic Chem.*, 2, 218 (1965); (d) R. J. Sundberg, *Tetrahedron Letters*, 477 (1966).

(8) Studies in these and in other laboratories<sup>7b</sup> indicate that I can be obtained in good yield by the reaction of *o,o'*-dinitroazobenzene with trialkyl phosphites. The nitrophenyltriazole IX may be an intermediate in this reaction.

mation of phosphinimine (e.g., XIII) with subsequent elimination of triethyl phosphite may likewise give the nitrene XIV. Finally, intramolecular displacement of the phosphite group in XIII by a triazole may lead directly to the azapentalene.

The last two sequences were shown to be highly likely when the phosphinimine XIII (prepared from the corresponding azide and triethyl phosphite) failed to yield I on pyrolysis in refluxing xylene.

**Chemical Properties.** The chemical reactivity of dibenzotetraazapentalene III (e.g., in electrophilic substitution reactions) parallels closely that reported for isomeric 1,3a,4,6a system I.<sup>3</sup>

Mononitration occurred in 25% nitric acid at room temperature. Dinitro and tetranitro derivatives at 0–5° in 70 and 90% nitric acid, respectively. Reaction of III with chlorine or chlorosulfonic acid gave the corresponding dichloro and bis(chlorosulfonate) derivatives, respectively. Although the positions of substitution in these electrophilic reactions have not been rigorously proved, charge density and localization considerations similar to those employed for the 6a isomer I<sup>3,4</sup> favor positions a and b as sites for

The tri- and tetranitro derivatives of I and positive Janovski reactions,<sup>9</sup> while the mononitro derivatives did not. Two nitro group tetranitro derivative were readily replaced by a diazo group in a manner similar to that of the 1,3a,4,6a system I, yielding the corresponding dinitro diazide.

III reacted slowly with methyl iodide at 100° to form an unstable adduct which could be isolated in pure state. On the other hand, treatment of III in concentrated sulfuric acid with refluxing led smoothly to an N-isopropyl methanesulfonate, which was converted to the iodide for characterization.

Catalytic hydrogenation of III (palladium catalyst, 125°) resulted in a rupture of the pentalene moiety.

(9) Aromatic systems with two or more *meta*-positioned nitro groups generally react at the doubly activated position (*ortho* to one nitro group and *para* to the other) with alkaline acetone to form an intensely colored nitrophenyl anion. See, for instance, R. Foster and R. K. Mackie, *Tetrahedron*, 19, 691 (1963).

carbon tetrachloride-chloroform bath. A solution of 18 g of sodium nitrite in 50 ml of water was added dropwise at  $-20$  to  $-22^\circ$ . The solution was stirred for 2 hr, and a solution of 18 g of sodium azide in 50 ml of water was added dropwise at  $-20$  to  $-22^\circ$ . Ether was added to minimize frothing. After being stirred for 3 hr, the solution was warmed to room temperature, neutralized with sodium hydroxide solution, and extracted with ether. The ether layer was dried over magnesium sulfate, and solvent was removed under vacuum to a volume of 300 ml. Hexane (250 ml) was added, and 22.2 g (51%) of white crystals of VII was collected. A portion recrystallized from ether melted at  $70.3\text{--}71.2^\circ$ ;  $\lambda$  335 (sh)  $\mu\text{m}$  ( $\epsilon$  82),  $\lambda_{\text{max}}$  254  $\mu\text{m}$  ( $\epsilon$  12,100),  $\lambda$  235 (sh)  $\mu\text{m}$  ( $\epsilon$  11,700);  $\nu_{\text{max}}$  3120, 2250, 2220, 1600 m, 1510 m, 1480 m, 1470 m, 1318, 1270 w, 1236, 1195 m, 1160 m, 1133 w, 1108 m, 1090 m, 1042, 1032 m, 986 m, 955 w, 945 w, 810, 758, 735 w, 710 m, and 700  $\text{cm}^{-1}$ .

*Anal.* Calcd for  $\text{C}_8\text{H}_8\text{N}_4$ : C, 51.61; H, 3.25; N, 45.15. Found: C, 51.91; H, 3.40; N, 44.88.

**Benzo-1,3a,6,6a-tetraazapentalene (IV).** A solution of 25.4 g (0.136 mole) of the azide VII in 75 ml of *o*-dichlorobenzene was heated in an oil bath at  $175\text{--}200^\circ$ . When gas evolution (0.14 mole total) had ceased, the solvent was removed under reduced pressure (2.0 mm) at  $80^\circ$  in a rotary film evaporator. The residue in methylene chloride was eluted continuously through a column of 400 ml of Woelm neutral alumina. (A heavy-liquid continuous extraction apparatus can be conveniently adapted for this purpose.) Solvent was distilled from the eluate to yield 11.24 g of IV. Recrystallization from ethanol yielded 9.45 g (44%) in two crops, mp  $121.6\text{--}122.2^\circ$ ,  $\lambda_{\text{max}}$  (concentrated hydrochloric acid) 311  $\mu\text{m}$  ( $\epsilon$  14,100), 267 (5450), 238 (9390), and 222 (14,970) (see Table I for ethanol solvent);  $\nu_{\text{max}}$  3150 m, 1620 m, 1582 w, 1512 m, 1478, 1440 w, 1375, 1340, 1330 m, 1305 m, 1280 m, 1196 w, 1186 w, 1157, 1137, 1110 w, 1080 m, 1007, 983 w, 978 m, 863 m, 810, 747, 734, 727, and 700  $\text{cm}^{-1}$ .

*Anal.* Calcd for  $\text{C}_8\text{H}_8\text{N}_4$ : C, 60.75; H, 3.82; N, 35.43. Found: C, 60.97; H, 3.38; N, 35.71, 35.76.

This compound could also be prepared in 36% yield by heating to reflux overnight a solution of 1.14 g of V and 4.0 g of trimethyl phosphite in 10 ml of xylene.

**Silver nitrate complex** was formed in 89% yield from acetonitrile solutions of IV and silver nitrate; white crystals, mp  $200^\circ$  dec.

*Anal.* Calcd for  $\text{C}_8\text{H}_8\text{N}_4 \cdot \text{AgNO}_3$ : C, 29.29; H, 1.84; N, 21.35. Found: C, 29.29, 29.19; H, 2.45, 2.10; N, 21.44.

**Cupric chloride complex** was prepared in 95% yield by the addition of 1.0 g of cupric chloride dihydrate to a solution of 0.50 g of IV in 50 ml of warm ethanol; blue-black crystals, mp  $179\text{--}182^\circ$ .

*Anal.* Calcd for  $\text{C}_{12}\text{H}_8\text{N}_4 \cdot \text{CuCl}_2$ : C, 32.84; H, 2.07; N, 19.15; Cu, 21.72. Found: C, 33.73; H, 2.14; N, 19.16; Cu, 21.04.

**Mercuric chloride complex** was formed in 27% yield from 0.6 g of mercuric chloride and a solution of 0.2 g of IV in 5 ml of ethanol; white crystals, mp  $170\text{--}172^\circ$ .

*Anal.* Calcd for  $\text{C}_8\text{H}_8\text{N}_4 \cdot \text{HgCl}_2$ : C, 22.36; H, 1.41; N, 13.04. Found: C, 22.63; H, 1.84; N, 13.18.

**Manganese chloride complex** was prepared in 20% yield from 1.97 g of manganese chloride tetrahydrate and 1.58 g of IV in 150 ml of warm ethanol; yellow, water-sensitive crystals, mp  $310\text{--}315^\circ$ .

*Anal.* Calcd for  $\text{C}_8\text{H}_8\text{N}_4 \cdot \text{MnCl}_2$ : C, 33.83; H, 2.13; Mn, 19.34. Found: C, 33.98; H, 2.26; Mn, 19.25.

**Dimethyl 1-(*o*-Nitrophenyl)-1H-triazole-4,5-dicarboxylate (X).** A solution of 41 g of *o*-azidonitrobenzene and 40 g of dimethyl acetylenedicarboxylate in 25 ml of chloroform was held at  $30^\circ$  for 15 days. The crystalline adduct (35.7 g) was separated by filtration and washed with 1:3 chloroform-hexane. The combined filtrates and washings were warmed to  $70^\circ$  for 2 hr, and volatile products were removed under reduced pressure ( $100^\circ$  (0.5 mm)). The residue was recrystallized from 80% methanol to yield an additional 23.8 g of adduct. A portion recrystallized successively from methanol-water and from benzene-hexane melted at  $87.5\text{--}88^\circ$ ;  $\nu_{\text{max}}$  1730, 1610 m, 1590 w, 1535, 1505 m, 1452 m, 1440 m, 1378 m, 1348, 1305, 1258, 1220, 1208, 1168 w, 1107, 1080 w, 1008, 962 m, 937 m, 853, 830 m, 810 m, 788, 748, 728 w, and 695  $\text{cm}^{-1}$ .

*Anal.* Calcd for  $\text{C}_{12}\text{H}_8\text{N}_6\text{O}_4$ : C, 47.06; H, 3.29; N, 18.30. Found: C, 47.20; H, 3.44; N, 18.36.

**Dimethyl 4,5-Benzo-1,3a,6,6a-tetraazapentalene-2,3-dicarboxylate (XI).** Under nitrogen a solution of 7.0 g of triethyl phosphite in 50 ml of toluene was added over 24 hr to a refluxing solution of 6.12 g of X in 100 ml of toluene. The solution was heated to reflux for 6 hr, and solvent and volatile products were removed under reduced pressure. The resulting oil crystallized partially. The white crystals (1.35 g) were dried on a clay plate, and after successive

recrystallization from methanol and benzene-hexane melt  $127.0\text{--}128.4^\circ$ ;  $\lambda_{\text{max}}$  353  $\mu\text{m}$  ( $\epsilon$  14,400), 284 (9650), 250 (18 and 223 (16,200);  $\nu_{\text{max}}$  4140 w, 4100 w, 3960 w, 1740, 1705, 1512, 1480 m, 1445 m, 1430 m, 1395 m, 1382, 1345, 1344, 1312, 1295, 1238, 1212 m, 1195 m, 1160 m, 1122 m, 1048 m, 1030 w, 970, 892 w, 862, 808, 756, and 714  $\text{cm}^{-1}$ .

*Anal.* Calcd for  $\text{C}_{12}\text{H}_{10}\text{N}_4\text{O}_4$ : C, 52.85; H, 3.68; N, 12.50. Found: C, 52.86; H, 3.76; N, 20.50.

**Methyl 4-Methoxy-*o*-triazolo[3,4-*a*]quinoxaline-3-carboxylate (XII).** A solution of 8.46 g of tributylphosphine in 50 ml of toluene was added slowly over 50 hr to a refluxing solution of 1.0 g of V in 50 ml of toluene. The resulting gray crystals (1.97 g) dried on a clay plate and washed with pentane. After two crystallizations from methanol the white crystalline product melted at  $193.8\text{--}195.0^\circ$ ;  $\lambda_{\text{max}}$  331  $\mu\text{m}$  ( $\epsilon$  11,420), 317 (13,400), 305 (291 (7500), 280 (7530), 265 (8520), 249 (13,900), and 222 (24  $\nu_{\text{max}}$  3100 w, 2950 w, 1635, 1578, 1552, 1490 m, 1480 m, 1385, 1335, 1320 m, 1283 w, 1265, 1247, 1230 m, 1210, 1186, 1109, 1007, 970, 900 m, 793 m, 769, 764, 735 m, 720 w, 713  $\nu_{\text{max}}$  688  $\text{cm}^{-1}$ ; nmr  $\tau$  1.9–2.4 (4), multiplet, 5.65 (3), and 5.83 (3).

*Anal.* Calcd for  $\text{C}_{12}\text{H}_{10}\text{N}_4\text{O}_4$ : C, 55.81; H, 3.90; N, 12.50. Found: C, 55.85; H, 4.02; N, 21.55.

**Dinitrobenzo-1,3a,6,6a-tetraazapentalene.** Compound IV (1.95 g) was added in small portions to 100 ml of 70% nitric acid at with stirring. The solution was stirred for 15 min at  $0^\circ$  and then allowed to warm to room temperature. The resulting crystals (1.95 g) of dinitro derivative were separated by filter and after recrystallization from 400 ml of acetone melted at  $280^\circ$ ;  $\lambda_{\text{max}}$  420  $\mu\text{m}$  ( $\epsilon$  20,900), 348 (6130), 338 (6130), 312 (11 278 (sh) (8300), 270 (9380), and 250 (11,900).

*Anal.* Calcd for  $\text{C}_8\text{H}_8\text{N}_4\text{O}_4$ : C, 38.72; H, 1.62; N, 34.09. Found: C, 38.74; H, 1.83; N, 34.09.

**Trinitrobenzo-1,3a,6,6a-tetraazapentalene.** Compound (5.7 g) was added in small portions to 75 ml of 95% (yellow fu nitric acid at  $0\text{--}5^\circ$  with stirring. The solution was warm room temperature, poured onto ice, and filtered. The olive- $\alpha$  product weighed 7.50 g. After successive recrystallizations acetone and 1:1 acetone-ethanol, it melted at  $305\text{--}306.5^\circ$ ;  $\lambda_{\text{max}}$  434  $\mu\text{m}$  ( $\epsilon$  27,900), 335 (5300), and 294 (16,400); nmr  $\text{CD}_2\text{SOCD}_2\text{--CH}_2\text{COCH}_3$   $\tau$  0.43 (1), doublet ( $J = 2.1$  cps) (1), 0.82 (1), doublet ( $J = 2.1$  cps).

*Anal.* Calcd for  $\text{C}_8\text{H}_8\text{N}_4\text{O}_7$ : C, 32.77; H, 1.03; N, 33.51. Found: C, 32.62; H, 1.12; N, 33.51.

**Tricyanovinylbenzo-1,3a,6,6a-tetraazapentalene (XVIII).** A solution of 0.84 g of IV in 10 ml of dimethylformamide (DMF) treated with a solution of 0.70 g of tetracyanoethylene in 10 ml of DMF. The initial greenish blue color of the complex gradually changed to purple. The solution was warmed on the steam bath for 30 min and was then poured onto 200 ml of crushed ice stirred for 15 min. The precipitated purple crystals (0.85 g) filtered and washed with water. A portion after recrystallization from benzene-hexane melted at  $236\text{--}237.4^\circ$ ;  $\lambda_{\text{max}}$  (acetone) 534  $\mu\text{m}$  ( $\epsilon$  24,700), 333 (6470), 310 (6310), 278 (4730), and (19,050);  $\nu_{\text{max}}$  3120 w, 2210, 1565 w, 1522, 1493, 1440, 1413 m, 1360, 1313, 1270, 1207, 1170, 1152, 890 w, 863 w, 782 m, 757, 748 m, 737 m, 694 m, and 668  $\text{cm}^{-1}$ .

*Anal.* Calcd for  $\text{C}_{11}\text{H}_8\text{N}_7$ : C, 60.23; H, 1.94; N, 33.51. Found: C, 60.01; H, 2.23; N, 37.62.

**1(6)-Methylbenzo-1,3a,6,6a-tetraazapentalenium Iodide.** A solution of 0.30 g of IV and 10 ml of methyl iodide was sealed in a tube and heated for 20 hr at  $100^\circ$ . The yellow crystalline product (0.46 g) was separated by filtration and washed with carbon tetrachloride, mp  $193.6\text{--}194^\circ$  dec. The product was very soluble in water, slightly soluble in acetonitrile;  $\lambda_{\text{max}}$  ( $\text{H}_2\text{O}$ ) 309  $\mu\text{m}$  ( $\epsilon$  12 222 (38,100);  $\lambda_{\text{max}}$  (ethanol) 318  $\mu\text{m}$  ( $\epsilon$  10,300), 268 (245 (sh) (8340), and 225 (31,500); nmr ( $\text{D}_2\text{O}$ )  $\tau$  1.02 (1), doublet ( $J = 2$  cps), 1.43 (1), doublet ( $J = 2$  cps), 1.70 (1), multiplet (3), multiplet, and 5.70 (3);  $\nu_{\text{max}}$  3070, 3020 m, 1620 m, 1490 w, 1472 w, 1450, 1430, 1380, 1340 m, 1315 m, 1185, 1135, 1012 m, 935 m, 880 w, 860 w, 788 m, 757 vs, and 700  $\text{cm}^{-1}$ .

*Anal.* Calcd for  $\text{C}_8\text{H}_8\text{N}_4\text{I}$ : C, 36.02; H, 3.02; N, 18.90. Found: C, 36.04, 36.27; H, 3.02, 3.17; N, 18.90.

**Dibenzo-1,3a,6,6a-tetraazapentalene (I)<sup>1,2</sup>** was isolated in 82% yield by treating IX<sup>2</sup> with 3.1–4.1 moles of triethyl or tri-*n*-butyl phosphite for 17 hr in refluxing xylene. When the solution cooled, nearly pure I crystallized. When IX was heated for 3 hr in refluxing xylene with 3.0 moles of tri-*n*-butyl phosphite, I was isolated in 75% yield.

**Dibenzo-1,3a,6,6a-tetraazapentalene (III)<sup>3</sup>** was isolated in 61% yield when VIII was heated for 20 hr in refluxing xylene with

les of triethyl phosphite. When triphenyl phosphite (neat) substituted, only 17% of III was isolated after 96 hr at 100°.

**nitrate complex** was prepared in 100% yield by mixing a solution of 11 g of III in 700 ml of warm tetrahydrofuran with a solution of 20 g of silver nitrate in 100 ml of acetonitrile; white solid, mp 282.5–283.5°.

**l.** Calcd for  $C_{13}H_8N_4 \cdot AgNO_3$ : C, 38.12; H, 2.13; N, 18.40. Found: C, 38.23; H, 2.57; N, 18.40.

**chloride complex** was formed in 87% yield by treating a solution of 0.42 g of III in 150 ml of warm ethanol with 50 g of copper(II) chloride dihydrate; bronze crystals, mp 281–284° dec.

**l.** Calcd for  $C_{13}H_8N_4 \cdot CuCl_2$ : C, 42.06; H, 2.36; N, 16.35; Cu, 39.54. Found: C, 43.10; H, 2.69; N, 16.47; Cu, 17.62.

**triethyl N-[o-(Benzo-2H-triazol-2-yl)phenyl]phosphorimidate**

A solution of 16.6 g of triethyl phosphite in 50 ml of benzene was added dropwise to a solution of 20.8 g of 2-(o-azidophenyl)-1H-benzotriazole in 200 ml of benzene. When nitrogen evolution ceased, unreacted phosphite and solvent were removed under reduced pressure. The oily residue (32 g) was crystallized from benzene at 5°, mp 28.7–31°;  $\lambda_{max}$  284 m $\mu$  ( $\epsilon$  11,420) and 237 (16,500);  $\nu_{max}$  3060 w, 2980 m, 2900 w, 1602, 1570 w, 1508 m, 1475 s, 1382, 1360 m, 1340 m, 1292 m, 1263 w, 1215 m, 1170 m, 1132 m, 1112 m, 1025, 968, 828 w, 790 m, 748, and 705 m.

**l.** Calcd for  $C_{18}H_{13}N_5O_3P$ : C, 57.76; H, 6.26; N, 14.97. Found: C, 57.81; H, 5.98; N, 15.09.

Although this compound decomposed slowly when heated at 100° in the infrared spectrum of the product provided no evidence for the presence of III.

**1,3a,6,6a-tetraazapentalene.** A solution of 5.0 g of III in 200 ml of methylene chloride was stirred vigorously with 25% nitric acid for 7 days. The organic layer was separated and dried with magnesium sulfate. Solvent was removed, and the residue was crystallized from 2.5 l. of boiling 95% ethanol to give 1.23 g of golden yellow platelets. After two recrystallizations from chloroform the mononitro derivative melted at 285–286°;  $\lambda_{max}$  313 (11,700), 275 (8930), and 230 (30,700). **l.** Calcd for  $C_{13}H_7N_5O_2$ : C, 56.90; H, 2.79; N, 27.66. Found: C, 57.15; H, 2.85; N, 27.91.

**1,3a,6,6a-tetraazapentalene.** Five grams of III was added in small portions to 100 ml of concentrated (70%) nitric acid at 0–5°. A vigorous reaction occurred, and 6.4 g of dinitro derivative separated. A portion recrystallized from acetone melted at 400–403° dec;  $\lambda_{max}$  424 m $\mu$  ( $\epsilon$  36,700), 260, 274 (14,300), and 237 (32,400).

**l.** Calcd for  $C_{13}H_5N_5O_4$ : C, 48.33; H, 2.03; N, 28.18. Found: C, 48.06; H, 2.01; N, 28.36.

**1,3a,6,6a-tetraazapentalene** was prepared by the successive addition of III or its mono- or dinitro derivatives (described above) to ice-cold yellow fuming (95%) nitric acid. The mixture was warmed briefly and poured onto ice. The resulting dinitro derivative was recrystallized from boiling acetone, mp 129–130° dec;  $\lambda_{max}$  450 m $\mu$  ( $\epsilon$  54,400), 375 (3240), 308 (17,180), 260 (12,980), and 207 (39,200);  $\nu_{max}$  3070 m, 1630 m, 1595 m, 1452 m, 1410, 1375, 1325, 1258, 1190 m, 1165 m, 1116, 1073 m, 869 m, 832 m, 773, 718 m, 740, 728, and 690 cm $^{-1}$ .

**l.** Calcd for  $C_{13}H_4N_5O_3$ : C, 37.12; H, 1.04; N, 28.86. Found: C, 36.81; H, 1.46; N, 28.66.

**1,3a,6,6a-tetraazapentalenebis(sulfonyl chloride).** One gram of III was dissolved cautiously in 10 ml of chlorosulfonic acid and the temperature of the solution was slowly raised to 90°. After 30 min at this temperature the solution was cooled and was poured cautiously onto ice. The solid product was separated by filtration, washed thoroughly with water, and air dried. After two recrystallizations from acetic acid–carbon tetrachloride, the pale crystals melted at 263–265° dec.

**Anal.** Calcd for  $C_{13}H_4N_5S_2O_4Cl_2$ : C, 35.58; N, 13.83; S, 15.83. Found: C, 35.62; N, 13.53; S, 15.29.

**1-Isopropylidibenzo-1,3a,6,6a-tetraazapentalenium Iodide.** A stream of propylene was passed for 20 min through a solution of 4.3 g of III in 25 ml of concentrated sulfuric acid at 0°. The solution was allowed to warm to room temperature, and the gas stream was continued for 20 min. The cloudy solution was poured onto 400 g of ice. After standing overnight, the solution was neutralized with sodium bicarbonate and then allowed to stand for 2 weeks. It was then filtered, and a solution of 15 g of sodium iodide in 50 ml of water was added. The whitish precipitate (4.2 g) was separated by filtration. A portion recrystallized from methylene chloride–hexane melted at 174° dec;  $\lambda_{max}$  276 m $\mu$  ( $\epsilon$  5480), 338 (22,900), and 348 (sh) ( $\epsilon$  21,000); nmr ( $CD_2SOCD_3$ )  $\tau$  0.9–2.4 (8), multiplet, 4.20 (1), septet ( $J$  = 6.5), and 8.17 (6), doublet.

**Anal.** Calcd for  $C_{13}H_{13}N_4I$ : C, 47.63; H, 4.00; N, 14.81. Found: C, 47.50; H, 3.99; N, 14.54.

**1-(o-Aminophenyl)-4,5,6,7-tetrahydro-1H-benzotriazole (XV).** A solution of 45 g of III in 650 ml of ethanol was hydrogenated at 125° and 1000 psi with 3 g of 5% palladium-on-carbon catalyst. The resulting solution was filtered, and solvent was removed under reduced pressure. The residual oil was crystallized from a mixture of 85 ml of benzene and 150 ml of hexane to yield 14.1 g (30%) of XV in two crops. A portion recrystallized from benzene–hexane melted at 115.5–116.2°;  $\lambda_{max}$  299 m $\mu$  ( $\epsilon$  3470) and 231 (15,000);  $\lambda_{max}$  3460, 3380, 3210 m, 2970, 2950, 2850 w, 1635, 1585 m, 1512, 1475 m, 1462 m, 1450 m, 1382 m, 1315 m, 1292 m, 1270 w, 1250 m, 1240 w, 1218, 1158 m, 1136 m, 1088, 1035 w, 1004, 963 m, 934, 848 m, 767, 721 w, and 703 w cm $^{-1}$ .

**Anal.** Calcd for  $C_{12}H_{11}N_4$ : C, 67.26; H, 6.58; N, 26.16. Found: C, 67.49; H, 6.91; N, 26.25.

**1-(o-Azidophenyl)-4,5,6,7-tetrahydro-1H-benzotriazole (XVI).** A solution of 13.9 g of XV in 250 ml of 22% hydrochloric acid was poured onto 150 g of ice and was diazotized at –20 to –25° with a solution of 4.8 g of sodium nitrite in 30 ml of water. The mixture was stirred for 1 hr at –25°, and a solution of 5.0 g of sodium azide in water was added slowly at –20 to –25°. Ether was added to suppress foaming. The resulting solution was allowed to warm slowly to room temperature. It was made alkaline with potassium hydroxide, and the precipitated solid (11.7 g, 75%) was recrystallized from benzene–hexane; mp 105–106.5°;  $\lambda_{max}$  248 m $\mu$  ( $\epsilon$  12,300).

**Anal.** Calcd for  $C_{12}H_{11}N_6$ : C, 59.98; H, 5.03; N, 34.98. Found: C, 60.53; H, 5.27; N, 35.72.

**4,5-Tetramethylene-2,3-benzo-1,3a,6,6a-tetraazapentalene (XVII).** A solution of 8.0 g of XVI in 50 ml of o-dichlorobenzene was added slowly to 40 ml of o-dichlorobenzene in a flask immersed in an oil bath maintained at 180°. After 1 hr nitrogen evolution had ceased. Solvent was removed under reduced pressure (70° (0.3 mm)), and the residue was dissolved in methylene chloride and eluted continuously with methylene chloride through a column of Woelm neutral alumina.

The eluate was evaporated under reduced pressure, and the resulting nearly white crystals (3.75 g, 53%) were recrystallized from ethanol and from methanol to yield shiny colorless leaflets melting at 176.5–177.5°. A second crystalline modification could also be isolated (see Table I for ultraviolet absorptions);  $\nu_{max}$  3060, 2940, 2850 w, 1615, 1582, 1510, 1480, 1445, 1432 m, 1405 m, 1372, 1335 m, 1245 m, 1230, 1208 m, 1128, 1080 m, 1020, 995, 970, 922, 893, 872, 837, 818 m, 744, 731, 732, and 693 m cm $^{-1}$ .

**Anal.** Calcd for  $C_{15}H_{13}N_4$ : C, 67.90; H, 5.70; N, 26.40. Found: C, 68.07; H, 5.71; N, 26.17, 26.41, 26.42.

This compound, like III, formed a blue complex with tetracyanoethylene, but did not react further in DMF solution, and so did not yield a tricyanovinyl analog of XVIII.

# Aromatic Azapentalenes. IV. Heats of Combustion of Monobenzo- and Dibenzo-1,3a,6,6a-tetraazapentalenes and Monobenzo- and Dibenzo-1,3a,4,6a-tetraazapentalenes. The Structure of Tetraazapentalenes

Y. T. Chia and H. E. Simmons

Contribution No. 1171 from the Central Research Department, Experimental Station, E. I. du Pont de Nemours and Company, Wilmington, Delaware.

Received November 17, 1966

**Abstract:** Precise heats of combustion and sublimation were determined for four derivatives of the recently synthesized 1,3a,6,6a- and 1,3a,4,6a-tetraazapentalene ring systems. The heats of formation referred to the gas phase in standard states were determined to be: dibenzo-1,3a,4,6a-tetraazapentalene (I),  $142.8 \pm 1.3$  kcal/mole; dibenzo-1,3a,6,6a-tetraazapentalene (II),  $132.1 \pm 1.5$  kcal/mole; monobenzo-1,3a,4,6a-tetraazapentalene (III),  $136.4 \pm 1.2$  kcal/mole; and monobenzo-1,3a,6,6a-tetraazapentalene (IV),  $128.2 \pm 1.3$  kcal/mole. From resonance energy considerations, these molecules appear aromatic in the usual thermodynamic sense. The aromaticity of the ten  $\pi$ -electron tetraazapentalene nuclei is discussed theoretically.

Previous papers in this series<sup>1</sup> have shown that dibenzo-1,3a,4,6a-tetraazapentalene (I), dibenzo-1,3a,6,6a-tetraazapentalene (II), and their monobenzo analogs III and IV have chemical properties that indicate the ten  $\pi$ -electron tetraazapentalene nuclei are aromatic. In the present paper the results of measurements of the heats of combustion and sublimation of I-IV are given, and the structure and spectra of these compounds are discussed in more detail.

## Experimental Section

**A. Purification of Compounds.** The compounds studied (I-IV) were purified by recrystallization from organic solvents and sublimation, and then by temperature-gradient sublimation. Infrared, ultraviolet, and mass spectral analyses were used to assay the final products, which were judged to be of high purity.

**B. Heat of Combustion Measurements.** The apparatus and procedures recommended by Jessup<sup>2</sup> were generally used with the following exceptions. The Mueller bridge was connected to a microvolt-indicating amplifier (both obtained from Leeds and Northrup Co.), and the latter was then connected to a recorder. Thus, the time of each of the different resistance settings at the "fast temperature change period" and the resistance measurements (to the fifth decimal place) during the initial and final periods were obtained from the chart of the recorder.

The calorimeter used was manufactured by Precision Scientific Co. (National Bureau of Standards Calorimeter Catalog No. 63090, Serial No. 10-R-4) and was calibrated by combustion of benzoic acid (National Bureau of Standards Sample No. 39i).

(2) R. S. Jessup, National Bureau of Standards Monograph No. 7, U. S. Department of Commerce, Washington, D. C., Feb 26, 1960.

The energy equivalent of the calorimeter was 5022.0 cal in a val 25.0–27.0° and was determined initially by an average combustions with a standard deviation of 0.016%. The tion was checked periodically, but no significant change tected during the measurements.

A Parr bomb (no. 1101 double valve) was used for the cor however, in order to permit mass spectral analysis of the products of the combustion, a plain Hoke valve was use outlet valve.

The tetraazapentalenes I-IV were very difficult to burn samples could be burned completely, but the temperature the accuracy were insufficient. By using a sample of benzoic acid as binder (wt % of benzoic acid = 35%), it sible to achieve complete combustion (confirmed by mass analysis) of samples of adequate size. Both the benzoic the tetraazapentalene were ground separately and weigh two were then thoroughly mixed and ground again in mortar, and desired amounts of the mixture were remc pelletized. The percentage composition of the pellet was to be the same as the composition of the mixture before p

A total of 1 ml of conductivity-grade water was introd the bomb with half the water placed in a platinum cup combustion crucible to ensure solution of all the nitroge produced.<sup>3</sup> Mass spectrometry consistently showed the of NO<sub>2</sub> in the gas products.

In order to make sure that none of the nitrogen in the pentalenes was further oxidized to N<sub>2</sub>O, NO, or other oxidation products of nitrogen, mass spectrometry was analyze the gas product from the combustion. No eviden other nitrogen compounds except N<sub>2</sub> in the final gas pro found.

The washings of the bomb were titrated with standar hydroxide solution to determine the nitric acid formed, correction was used in the subsequent calculation of the combustion. The final solution was then analyzed for ni but none was ever detected.

**C. Vapor Pressure Measurements.** The McLeod gauge was used to measure the vapor pressure of I-IV as a fu temperature. A 1-l. bulb was attached to the McLec through a 2-mm capillary which was about 4 in. in length. trap was placed at the end of the capillary, and cold nitr blown through the cold trap whose temperature was periodically by a thermocouple. Nitrogen was used as gas in the system. A stainless steel wire soldered to a ma hung inside the tube above the cold trap. During the va sure measurements at higher temperatures, the stainless s could be moved up and down by an outside magnet to pr

ry tube from becoming plugged. The reference temperature  $10^\circ$  for the dibenzo derivatives I and II and  $0^\circ$  for the mono-derivatives III and IV. At the reference temperature, the pressure due to the sample studied was assumed to be negligible. Vapor pressures of the dibenzo derivatives were measured from  $90$  to  $160^\circ$  (or  $170^\circ$ ) and of monobenzo derivatives from  $100^\circ$  (or  $110^\circ$ ), both at  $10^\circ$  intervals. The apparatus was checked by measuring the vapor pressure of purified benzene at  $110$ ,  $120$ , and  $130^\circ$ , and the results agreed well with reported in the literature.<sup>5</sup>

## ts and Calculations

**Heat of Combustion Results.** The corrected temperature rise of a combustion run was computed using a least-squares straight line through the initial (min) and final (23–30 min) periods and computing arithmetically the appropriate integral. These computations were programmed for and carried out by an IBM computer.

As noted above, nitrogen dioxide was the only oxidation product of nitrogen detected in the combustion of the four tetraazapentalene derivatives; moreover, the nitrogen dioxide formed was dissolved in the water, forming nitric acid. Thus, the combustion reactions of the compounds studied can be written as

The energy of combustion could be calculated on the basis of the above equations from the corrected temperature rise with appropriate corrections for the formation of nitric acid. Table I summarizes the results of the combustion experiments. The first and second columns represent the weights in air of sample and benzoic acid, respectively, and the third column ( $\Delta E_c$ ) gives the total energy of combustion for the bomb process calculated from the corrected temperature rise.

The values of  $q_1$  and  $q_2$  are corrections for the fuse and nitric acid, respectively. The sixth column gives the fashburn corrections,<sup>6</sup> and  $\Delta E_B$  in the seventh column is the energy of combustion due to benzoic acid. The last column is the energy of combustion due to the sample and has been corrected to standard state, *i.e.*

$$-\Delta E_c^\circ = (-\Delta E_c - q_1 - q_2 - q_3 + \Delta E_B)/M$$

The average value of  $\Delta E_c^\circ$  was corrected finally for the density of air, and the uncertainty represents the standard deviation.

The standard state heats of combustion ( $\Delta H_c^\circ$ ) were calculated from the values of  $-\Delta E_c^\circ$  and the combustion reactions written above.<sup>7</sup> From the values of the heats of combustion (third column, Table II) and the heats of formation of water and carbon dioxide, the heats of formation [ $\Delta H_f^\circ(s)$ ] of the four tetraazapentalenes in solid form and standard state were derived and are reported in the last column of Table II.

lenes in solid form and standard state were derived and are reported in the last column of Table II.

The logarithm of the vapor pressures of the four compounds studied were plotted against the reciprocal of temperature. From the slopes of the straight lines obtained (Figure 1), it is possible to calculate the heats of sublimation at  $298^\circ\text{K}$  of these compounds. These values were also checked by the least-squares method and are listed in the fourth column of Table II; the uncertainty was also calculated by the least-squares method. No corrections were made for the variation of the heats of sublimation from the temperature range in which they were measured to  $298^\circ\text{K}$ . From the heats of sublimation and the heats of formation of the solid tetraazapentalene derivatives, it is possible to calculate the heats of formation referred to gaseous form in standard states. These are also listed in the last column of Table II.

As shown in Table II, the difference in heats of formation of I and II was found to be  $10.7$  kcal/mole, indicating that II is more stable than I. Similarly, IV was  $8.2$  kcal/mole more stable than III. These findings are in accord with theoretical considerations as discussed in the next sections.

## Discussion

**Resonance Energies.** The estimation of resonance energies is always fraught with uncertainties, and it is expected to be particularly so with molecules such as the tetraazapentalenes in which many formal struc-

VI, and (2) the charge-separated structures VII and VIII. The former structures emphasize that the ten  $\pi$  electron tetraazapentalene systems formally contain two

pyridine-like and two pyrrole-like nitrogen atoms. At first sight this seems to be a poor choice, since, e.g., VII has one more bond than V, and thus the empirical resonance energy might be overestimated when V is used as the basis. The energy of the extra bond is, however, largely offset by the large formal charge separation.

was determined from the heat of combustion of gaseous hydrazine ( $\Delta H_c^\circ = -154.99$  kcal/mole)<sup>9</sup> and was found to be  $\lambda(\text{N-N}) = 33.0$  kcal/mole. The heats of combustion of both I and II were found to be  $-1666.4$  kcal/mole. The resonance energies are then  $E_R(\text{I}) = 121.7$  kcal/mole and  $E_R(\text{II}) = 132.4$  kcal/mole. For series 2, the  $\text{N}=\text{N}$  bond contribution determined by Coates and Sutton<sup>10</sup> was employed,  $\lambda(\text{N}=\text{N}) = 34.2$  kcal/mole, giving a heat of combustion of  $-1667.6$  kcal/mole for both I and II. The resonance energies were thus determined to be  $E_R(\text{I}) = 122.9$  kcal/mole and  $E_R(\text{II}) = 133.6$  kcal/mole. The agreement between the two esti-

(10) G. E. Coates and L. E. Sutton, *J. Chem. Soc.*, 1187 (1948).

is very good. Because the models for I and II are formally equivalent with regard to kinds of bonds, the experimental heats of formation reflect the resonance energies directly.

It is seen that the more angular-shaped molecule II is 10.7 kcal/mole stable than the linear-shaped I. This behavior is typically that of pure benzenoid hydrocarbons where the analogs of I and II, naphthalene, chrysene, respectively, have resonance energies<sup>8</sup> of their own. Here the angular hydrocarbon is more stable

than the linear by 6.5 kcal/mole. It is interesting to note that the resonance energies of I and II are larger than those of their isoelectronic hydrocarbon counterparts.

If we consider that each benzene ring in I and II contributes roughly 36.0 kcal/mole to the resonance energy, the contributions of the 1,3a,4,6a- and 1,3a,6,6a-azapentalene nuclei in I and II, respectively, are 49.7 (50.9) and 60.4 (61.6) kcal/mole for the series 1 and 2, respectively. The naphthalene-like nuclei of naphthalene and chrysene contribute 38.0 and 48.0 kcal/mole, respectively, to the resonance on this basis.

Calculations using similar models for the monobenzo derivatives III and IV give theoretical heats of combustion of -1178.4 kcal/mole for series 1 and -1179.6 kcal/mole for series 2. The empirical resonance energies are  $E_R(\text{III}) = 84.7$  (85.9) kcal/mole and  $E_R(\text{IV}) = 94.0$  kcal/mole. The contributions of the tetraazapentalene nuclei are then 48.7 and 56.8 kcal/mole, respectively, in rough agreement with the values derived from the dibenzo derivatives.

**Electronic Structure of Tetraazapentalenes.** The relationship between the structure of the tetraazapentalene and the valence isomerization (e.g.,  $Z \rightarrow Z'$ ) which destroys aromaticity was discussed in paper I.<sup>1a</sup> HMO

MO theory predicts that the delocalization energy per  $\pi$  electron is larger in pentalene dianion than in a fictitious cyclooctatetraene, and the same situation prevails for the nitrogen analogs.

MO calculations were carried out for Z,  $C_1$ , and  $C_2$  assuming the reasonable parameters<sup>11</sup>  $\alpha_N = \alpha_C + \beta$  (pyrrole-like),  $\alpha_N = \alpha_C + \beta$  (pyridine-like), and  $\beta_{CC} = \beta_{NN}$ . If we base the delocalization energy of tetraazapentalene on one covalent structure such as Z, then the results in Table III are obtained.

A. Streitwieser, Jr., "Molecular Orbital Theory for Organic Chemists," John Wiley and Sons, Inc., New York, N. Y., 1961, p 135.

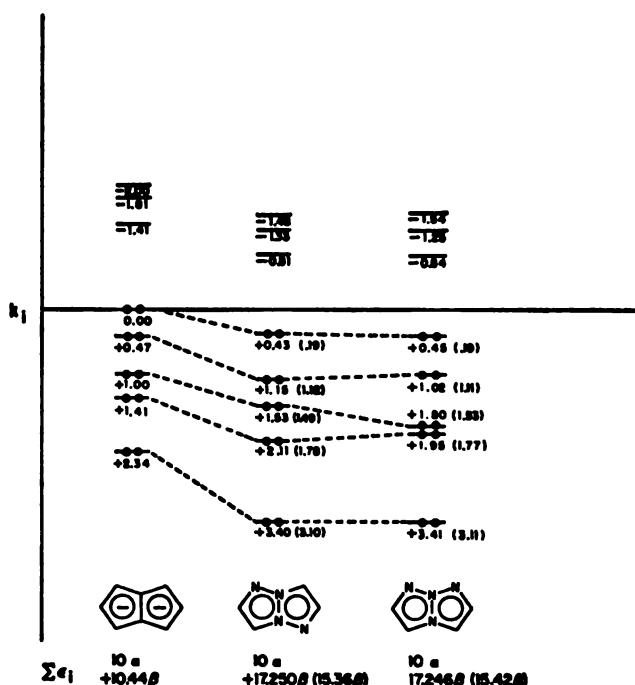

Figure 2. Energy level diagrams,  $e_i = \alpha + k_i\beta$ .

It is evident that the azapentalene structure is highly stabilized by electron delocalization on the basis of the delocalization energy per  $\pi$  electron, compared to either eight-membered ring structure. Since the latter structures would most likely exist in tub conformations, these values are also included, and it is seen that the azine form  $C_2$  is slightly preferred over the azo form  $C_1$ .

Table III. Energies of Z,  $C_1$ , and  $C_2$

	Total energy	Delocalization energy, $\beta^{-1}$	Delocalization energy/ $\pi$ electron
Z	$10\alpha + 17.250\beta$	4.421	0.44
$C_1$ (planar)	$8\alpha + 14.314\beta$	2.314	0.29
$C_1$ (tub form)	$8\alpha + 12.000\beta$	$\sim 0$	$\sim 0$
$C_2$ (planar)	$8\alpha + 14.314\beta$	1.369	0.17
$C_2$ (tub form)	$8\alpha + 12.944\beta$	$\sim 0$	$\sim 0$

The chemical reaction  $C_1$  (or  $C_2$ )  $\rightarrow$  Z involves the change of two nitrogen atoms from the valence state ( $\text{tr}^2\text{trtr}\pi$ ) to ( $\text{trtrtr}\pi^2$ ). This energy which amounts to 6.2 eV<sup>12</sup> must be less than the gain in  $\pi$ -delocalization energy plus the energy of the new N-N  $\sigma$  bond for this reaction to proceed. Therefore, since  $E_\sigma(\text{N-N}) \sim 2.6$  eV, then  $E_\pi(\text{Z}) - E_\pi(\text{C}_1) = 2\alpha + 5.25\beta$  must be greater than 3.6 eV. Any reasonable estimate of the integrals involved assures us that this is indeed so, and we conclude that the process  $C_1$  (or  $C_2$ )  $\rightarrow$  Z will be exothermic. Similar conclusions can be drawn about the tetraazapentalene nucleus in III.

Molecular orbitals were calculated for T, the nucleus of III, using the same integral values, and the energy level diagrams in Figure 2 compare Z, T, and pentalene dianion. First, it is to be noted that all bonding levels are displaced to lower energies as expected, when nitro-

(12) J. Hinze and H. H. Jaffé, *J. Am. Chem. Soc.*, **84**, 540 (1962).

gen is introduced into the nucleus of pentalene dianion. Second, it is clear that the *position of the nitrogen atoms has very little effect on the energy levels or the total energy*. This kind of behavior would be expected if the tetraazapentalene nucleus is aromatic and its  $\pi$  electrons highly delocalized. The bond orders and charge distribution of Z and T are also very similar, in further confirmation of this conclusion (Table IV).

Table IV. Bond Orders and Charge Densities of Z and T

These crude calculations are sufficient for our purpose of explaining the aromaticity of the tetraazapentalenes. The results suggest that Z and T are close in energy, and similar calculations on I and II show that the mono- and dibenzo derivatives have delocalization energies that do not depend much on the location of the nitrogen atoms. More accurate calculations indicate that II is slightly more stable than I, and this conclusion is in accord with precise thermodynamic data.

A better estimate of the energy levels of the azapentalenes can be made by considering their structures more closely. In an HMO calculation some means must be found for estimating the parameters, since a given nitrogen atom occurs successively in various valence states depending on the canonical structures. In the 1,3a,6,6a system there are 12 resonance structures like VII which are nonexcited in the Pauling sense. Presumably, most of these make significant contributions to the ground state, and monoexcited structures such as

will contribute to a lesser extent.

We estimate the HMO coulomb ( $h$ ) and resonance ( $k$ ) parameters in the following way. For each nitrogen in a fixed position a factor was determined that corresponds to the number of times it occurs as a pyridine, pyrrole, quaternary, and amide type. The usual Hückel

parameters suggested by Streitwieser<sup>11</sup> were then weighted by these factors to determine an average parameter for each nitrogen. The monoexcited structures were taken into account the same way, but weighted only one-tenth relative to the nonexcited. The  $\beta$ 's were determined similarly. In this manner, valence-bond structures were used to estimate the molecular orbital parameters. For our purpose, the systems are numbered as in V and VI. The resulting one-electron parameters are

V	VI
$h_2 = +0.383$	$h_2 = +0.388$
$h_3 = +1.733$	$h_3 = h_7 = +1.747$
$k_{23} = k_{37} = k_{34} = +0.80$	$k_{23} = k_{37} = k_{37} = +0.80$
$k_{12} = k_{45} = +1.00$	$k_{12} = k_{56} = +1.00$

The energy levels are given in parentheses in Table IV, and it is thought that these results are close to self-consistent values. The total energies of the dibenzo derivatives are  $E(I) = 18\alpha + 26.904\beta$ ,  $E(II) = 18\alpha + 27.002\beta$  and of the monobenzo derivatives,  $E(III) = 14\alpha + 21.152\beta$ ,  $E(IV) = 14\alpha + 21.210\beta$ . The corresponding delocalization energies based on the non-charge-separated structures are  $E_D(I) = 7.905\beta$ ,  $E_D(II) = 8.004\beta$ ,  $E_D(III) = 6.151\beta$ , and  $E_D(IV) = 6.213\beta$ . Isomer II is predicted to be more stable than I, and similarly IV more stable than III, in accord with the experimental heats of formation. It is expected that the difference in delocalization energies, e.g.,  $E_D(II) - E_D(I)$ , should be proportional to the difference in heats of formation. Thus,  $8.004\beta - 7.905\beta = 10.7$  kcal/mole, or  $\beta(\text{empirical}) = 108.1$  kcal/mole. It is calculated for the monobenzo derivatives than  $E_D(IV) - E_D(III) = 0.062\beta = 6.7$  kcal/mole, while the experimental value is 8.2 kcal/mole, in satisfactory agreement.

Charge distributions were calculated for I–IV, and the results are shown below. If electrophilic substitution in these molecules parallels electron density in the

ground state, then the 2 and 4 positions in the benzene rings of I and II should be preferentially nitrated, chlorinated, etc., and this seems to be the case.<sup>1b,c</sup> Electrophilic attack in the tetraazapentalene nucleus is predicted to occur preferentially at the positions marked by asterisks in III and IV, and substitution products<sup>1b,c</sup> are believed to have these structures. It is interesting to note that HMO calculations employing the usual parameters<sup>11</sup> for these charge-separated structures give charge distributions that make the benzene rings assume small net positive charges and predict incorrect orientation for electrophilic substitution. Experi-

ally, I and II are nitrated, for example, more readily than benzene, an observation in accord with the nearly self-consistent calculations.

The bond orders of the N-N central bonds in the azapentalene nuclei have the values  $\rho_{NN} = 0.300$  (II), 0.300 (III), 0.297 (IV). The bond orders of the C-C central bonds in pentalene dianion and naphthalene are  $\rho_{CC} = 0.531$  (PA), 0.518 (N), and the electron density in the central bond region is characteristic of normal aromatic structures. The approximate bond orders of the tetraazapentalenes in this region support the conclusion that these molecules are aromatic.

The ultraviolet spectra of I and II are complicated but are unlike those expected for fully aromatic structures. In naphthalene, which contains ten  $\pi$  electrons, the three lowest observed singlet states correspond to those predicted by Pariser-Parr theory (employing only excited configurations)<sup>13,14</sup> which occur at 4.18 ( $^1B_{2u}$ ), 4.48 ( $^1B_{2u}$ ), and 5.92 eV ( $^1B_{3u}$ ), and only transitions to the latter two are allowed. The  $B_{2u}$  state is derived from the configuration  $V_{66}$ , obtained by promoting an electron from MO 5 to MO 6. The two other states are obtained mostly from mixing of  $V_{67}$  and  $V_{46}$  which interact strongly because their energies are close. Although  $E(V_{66}) < E(V_{67}) = E(V_{46})$ , the former depresses one of the resulting  $B_{2u}$  states so that it actually occurs below the  $B_{2u}$  state.

The isoelectronic pentalene dianion shows two strong absorptions in the ultraviolet region<sup>15</sup> which agree with the spectrum calculated by Pariser-Parr configuration interaction theory.<sup>16</sup> The three lowest singlets corre-

sponding to those observed for naphthalene are predicted to occur at 4.57 ( $^1B_{2u}$ ), 5.12 ( $^1B_{2u}$ ), and 7.11 eV ( $^1B_{3u}$ ), and here all three are allowed. The states of same symmetry are formed primarily from the same configurations as in naphthalene, but the nonalternant character of the molecular orbitals precludes the strong degenerate mixing of  $V_{46}$  and  $V_{67}$ . Thus, the  $B_{2u}$  state is the lowest, in accord with the observation that  $E(V_{66}) < E(V_{67})$  or  $E(V_{46})$ . In pentalene dianion, the high-energy  $B_{3u}$  state occurs in the vacuum ultraviolet and has not yet been identified.

Three similar absorptions are expected to occur in the tetraazapentalenes Z and T. Inspection of Figure 2 shows that on going from pentalene dianion to Z,  $V_{66}$  decreases strongly in energy,  $V_{67}$  decreases only slightly, and  $V_{46}$  increases slightly. On going to T,  $V_{66}$  decreases less strongly than in Z,  $V_{67}$  decreases more strongly, and  $V_{46}$  decreases slightly. When two benzene rings are fused on Z and T to form I and II, the characteristic properties of the states in question are anticipated to be largely preserved.

Although the assignments for the spectra of I and II are yet unknown, it is reasonable that the three regions of absorption in them correlate with the three lowest energy configurations discussed above. From Table I in paper I we see that the two longest wavelength regions of I are indeed red shifted with respect to the aromatic hydrocarbon analog chrysene, and the highest energy absorption is blue shifted, as predicted. Also, in accord with expectation, the long-wavelength absorption of II is blue shifted with respect to that of I and occurs actually at about the same place as that in chrysene. The next two bands in II, however, are also blue shifted with respect to those in I. This crude picture is satisfying and is all we might have hoped for using such poor molecular orbitals as a basis and neglecting electron repulsion effects.

## Aromatic Azapentalenes. V. 1,1'- and 1,2'-Bibenzotriazoles and Their Conversion to Dibenzotetraazapentalenes

R. J. Harder, R. A. Carboni, and J. E. Castle

Contribution No. 1172 from the Central Research Department, Experimental Station, E. I. du Pont de Nemours and Company, Wilmington, Delaware.

Received November 17, 1966

**Abstract:** The syntheses, physical properties, and structural assignments for 1,1'-bibenzotriazole (4a) and 1,2'-bibenzotriazole (8) are described. Both 4a and 8 lose nitrogen on heating to give dibenzo-1,3a,4,6a-tetraazapentalene (1) and dibenzo-1,3a,6,6a-tetraazapentalene (2), respectively.

In earlier papers in this series,<sup>1,2</sup> the synthesis of benzo-1,3a,4,6a-tetraazapentalene (1) by thermal photochemical decomposition of *o,o'*-diazidoazone was described. This interesting heteroaromatic 1 has now been prepared by an alternative route, by A. Carboni and J. E. Castle, *J. Am. Chem. Soc.*, **84**, 2453

A. Carboni, J. C. Kauer, J. E. Castle, and H. E. Simmons, *ibid.*, **89**, 2618 (1967).

*i.e.*, through controlled thermal decomposition of 1,1'-bibenzotriazole (4). A similar thermolysis occurs with the isomeric 1,2'-bibenzotriazole (8) to form the corresponding dibenzo-1,3a,6,6a-tetraazapentalene (2).<sup>3</sup> This paper discusses the synthesis, proof of structure, and decomposition of the hexaaza compounds 4 and 8.

**1,1'-Bibenzotriazole.** The hexaaza derivative 4 was prepared in good yield from tetraazotized *o,o'*-diamino-

azobenzene. When sulfur dioxide was passed rapidly through a cold aqueous solution of the *o,o'*-azobenzene-bisdiazonium salt (3), the product 4 precipitated as a tan solid. Elemental analyses and molecular weight determinations on the purified colorless solid, mp 235° dec, are in accord with the empirical formula  $C_{12}H_8N_6$ .

The synthetic route to 4 and the subsequent decomposition to 1 suggest four possible structures, 4a-d, for the hexaaza product. These structures may form

by the addition of an electron to each diazonium group followed by addition of the resulting radicals to the azo group, either directly or with rearrangement of electrons.

Alternatively, 4a and b may form *via* the intermediate hydrazo derivative by reaction of the diazonium groups with (a) their respective  $\alpha$ -nitrogens (to give 4a) or (b) their respective  $\beta$ -nitrogens (to yield 4b). Intramolecular coupling of the first type occurs in the diazotization of *o*-phenylenediamine, where the intermediate *o*-aminobenzene-diazonium ion (5) reacts with the amino substituent to yield 1H-benzotriazole (6).<sup>3</sup> On the other hand, Zincke and Lawson<sup>4</sup> observed that treatment of *o*-(*p*-tolylazo)-*p*-toluenediazonium chloride (7) with a reducing agent such as stannous chloride or sulfur dioxide produced a crystalline product which was assigned the benzotetraazine structure 9.

The ultraviolet spectrum of 4 shows two absorption maxima, at 252  $m\mu$  ( $\epsilon$  14,630) and 288  $m\mu$  ( $\epsilon$  7790). Thus a strong resemblance to the absorption spectrum of 1H-benzotriazole and 1-methylbenzotriazole is evident (Figure 1), providing a preference for the 1,1'-

bibenzotriazole structure 4a. Compounds 4b and c which contain the aryl  $-N=N-N$  group in a six-membered ring would be expected to exhibit absorption at considerably longer wavelengths. For example, 3-phenyl-3,4-dihydro-1,2,3-benzotriazine exhibits an absorption maximum at 360  $m\mu$ .<sup>5</sup> Nuclear magnetic resonance (proton) spectroscopy was of little value for the structure proof, ill-defined spectra being obtained because of the low solubility of 4 in organic solvents.

Treatment of 4 with dimethyl sulfate gave successively a monoalkylation product 10 and a dialkylation product 11. Methosulfates 10 and 11 are both water soluble and can be readily converted to the corresponding isolable iodides. However, the hydroxide of

bismethosulfate 11 rapidly decomposed in water at room temperature to give 1 molar equiv of 1-methylbenzotriazole (12).<sup>6</sup> This provides a clear preference for the 1,1'-bibenzotriazole structure 4a, in agreement with the ultraviolet spectral data. Thus, the formation of 12 may be represented by the sequence 4a  $\rightarrow$  10  $\rightarrow$  11 shown in Figure 2.

Further evidence for the bisbenzotriazole structure was obtained by the facile reductive cleavage of the bismethosulfate 11 by lithium aluminum hydride. When an ether solution of 11 was treated with excess lithium aluminum hydride at room temperature, an excellent yield (93%) of 1-methylbenzotriazole (12) (2 molar equiv) was obtained. Presumably the same kind of scission occurs here as in the hydroxide decomposition.

(5) P. Ramart-Lucas and J. Hoch, *Bull. Soc. Chim. France*, 447 (1949).  
(6) 1-Methylbenzotriazole 2-N-oxide is assumed to be the other product of the hydroxide decomposition, but was not isolated.

Figure 1. Ultraviolet spectra of 1H-benzotriazole, —; 1-hyl-1H-benzotriazole, ---; and 1,1'-bibenzotriazole, -.-.

The formation of more than 1 molar equiv of the benzotriazole derivative 12 strongly favors structure 4a, since 4b-d all would require extensive rearrangements. The facile reduction of the bismethosulfate with sodium aluminum hydride is in sharp contrast to the stability of the unalkylated product 4 toward this agent. The reactivity of 11 is undoubtedly associated with its positive charges which should facilitate hydride ion attack. Finally, the reduction cleavage of 11 with sodium aluminum hydride in moist ether<sup>7</sup> to obtain somewhat greater than 1 molar equiv 1H-benzotriazole (6), thus providing additional evidence in favor of 1,1'-bibenzotriazole (4a).

**2'-Bibenzotriazole.** In view of the interesting thermal transformation exhibited by 1,1'-bibenzotriazole (4a), the synthesis of the isomeric 1,2'-bibenzotriazole (8) was undertaken. A convenient route was provided by the intermediate 2-aminobenzotriazole.<sup>8</sup> The preparative route to 8 is summarized in Figure 3. Reaction of 2-aminobenzotriazole (13) with *o*-fluoro-*o*-chloronitrobenzene in dimethylformamide in the presence of sodium carbonate gave 2-(*o*-nitrophenylino)-2H-benzotriazole (14) in 85% yield. Under similar conditions, 1-aminobenzotriazole (15)<sup>9</sup> gave only tars. Hydrogenation of 14 to 2-(*o*-aminophenylino)-2H-benzotriazole (16) was readily achieved in tetrahydrofuran with palladium on charcoal. Treatment of the amine 16 with nitrous acid gave a crystalline solid, mp 124°, to which we assign the structure 1,2'-bibenzotriazole (8). The preparation of 1-substituted 1H-benzotriazoles by diazotization of *N*-substituted *o*-phenylenediamines has ample precedent in the literature.<sup>2,10</sup> The ultraviolet spectrum (ethanol)

of 8 showed  $\lambda_{\max}$  250 mμ ( $\epsilon$  8700), 282 mμ ( $\epsilon$  17,600), and 290 mμ ( $\epsilon$  16,700), consistent with the assigned structure.

**Thermal Decomposition of the Bibenzotriazoles. Formation of Dibenzotetraazapentalenes.** When a solution of 1,1'-bibenzotriazole in di-*n*-butyl phthalate was heated at 300°, 1 mole of nitrogen was evolved with concomitant deepening in color of the solution. The well-defined, yellow, crystalline product obtained, mp 240–241°, was identified as dibenzo-1,3a,4,6a-tetraazapentalene (1) by comparison with an authentic sample. 1,2'-Bibenzotriazole (8) underwent a similar transformation at 250° with formation of the isomeric dibenzo-1,3a,6,6a-tetraazapentalene (2).

The mechanism for the tetraazapentalene formation in these thermolysis has not been studied. However, the reaction sequence may be represented as follows.

On heating, a molecule of azo nitrogen is eliminated from the 1H-benzotriazole moiety of each of the hexa-aza derivatives with incipient or intermediate formation of the 1,3-dipolar intermediates, 17 and 18, or their equivalents; subsequent bond formation between the ring carbon and the 2-N (in 17) and 1-N (in 18) yields the corresponding tetraazapentalenes 1 and 2, respectively.

The thermolysis is reminiscent of the Graebe-Ullmann synthesis of carbazoles from 1-phenylbenzotriazoles, although the latter reaction involves the formation of a carbon-carbon bond rather than a carbon-nitrogen bond and also involves migration of a hydrogen atom.<sup>11</sup>

The thermal stability of the nitrogen-nitrogen bonds between each ring in the bibenzotriazoles 4a and 8 is remarkably greater than those of the closely related lophine 19 and tetraphenylpyrrole dimer 20, which are measurably dissociated into the corresponding free radicals at temperatures below 100°.<sup>12</sup>

## Experimental Section<sup>13</sup>

**1,1'-Bibenzotriazole (4a).** To a mixture of 2.1 g (0.01 mole) of *o,o'*-diaminoazobenzene<sup>14</sup> in 25 ml of 12% hydrochloric acid was slowly added sodium nitrite (1.5 g, 0.022 mole) in 10 ml of water. The temperature was maintained at 0–5° during the addition and throughout the subsequent treatments. The clear, homogeneous diazotization mixture was stirred for an additional 30 min, then treated with sulfur dioxide. The latter was introduced in a moderately rapid stream with stirring. A solid began to separate almost immediately. After 20 min, the light tan precipitate (1.5 g, 63%) was collected by filtration and recrystallized from ethyl acetate, to

obtain colorless needles, mp 233° dec. A second recrystallization from decahydronaphthalene gave 4a as hairlike crystals, mp 235° dec.

*Anal.* Calcd for  $C_{12}H_8N_4$ : C, 61.0; H, 3.4; N, 35.6. Found: C, 60.8; H, 3.6; N, 35.6.

The ultraviolet spectrum (ethanol) shows  $\lambda_{max}$  252 m $\mu$  ( $\epsilon$  14,600) and 288 m $\mu$  ( $\epsilon$  7800). The dipole moment is 5.16 D. (0.02 M in benzene at 25°).

**2-(*o*-Nitrophenylamino)-2H-benzotriazole (14).** A mixture of 34 g (0.25 mole) of 2-aminobenzotriazole (13), 35 g (0.25 mole) of *o*-fluoronitrobenzene,<sup>15</sup> 25.4 g (0.24 mole) of anhydrous sodium carbonate, and 120 ml of dimethylformamide was refluxed under nitrogen for 2 hr. The red-brown mixture was cooled and poured into 2.5 l. of water, precipitating a yellow solid. The latter was collected on a filter, washed with water, and recrystallized from 95% ethanol, giving 55 g (85%) of 2-(*o*-nitrophenylamino)-2H-benzotriazole, mp 144–145°.

*Anal.* Calcd for  $C_{12}H_8N_4O_2$ : C, 56.47; H, 3.55. Found: C, 56.53; H, 3.47.

**2-(*o*-Aminophenylamino)-2H-benzotriazole (16).** A mixture of 10.2 g (0.04 mole) of 2-(*o*-nitrophenylamino)-2H-benzotriazole, 0.3 g of 10% palladium on charcoal, and 75 ml of tetrahydrofuran was shaken at room temperature in a Parr apparatus under 40 psi hydrogen pressure. Hydrogen uptake was rapid, the theoretical amount being consumed in 10 min. The mixture was filtered, and the filtrate was evaporated nearly to dryness under nitrogen. The dark, partially crystalline residue was taken up in 95% ethanol, treated with charcoal, filtered, and diluted with water, giving tan leaflets (7 g, 78%), mp 100° dec. Recrystallization from ethanol-water gave colorless leaflets, mp 106° dec.

*Anal.* Calcd for  $C_{12}H_{11}N_5$ : C, 63.98; H, 4.92; N, 31.10. Found: C, 63.13; H, 5.16; N, 31.06.

The infrared spectrum of this product is consistent with the proposed structure 16.

Because of the difficulties in obtaining this amine analytically pure, the slightly crude material was employed for conversion to 1,2'-bibenzotriazole.

**1,2'-Bibenzotriazole (8).** A solution of 6.0 g (0.0266 mole) of 2-(*o*-aminophenylamino)-2H-benzotriazole in 250 ml of 1 N hydrochloric acid was cooled to 0°, and a solution of 1.80 g (0.026 mole) of sodium nitrite in water was added dropwise with stirring. The gray precipitate was collected on a filter and dissolved in ether, and the solution was treated with charcoal and filtered. Evaporation of the solvent and subsequent crystallization of the residue from aqueous ethanol gave 4.0 g (63%) of pale tan crystals, mp 123.5–124.5°. The melt on cooling gave crystals which melted at 98°, formed a new solid phase at 102°, and remelted at 123.5–124.5°.

*Anal.* Calcd for  $C_{12}H_8N_4$ : C, 61.01; H, 3.41; N, 35.58; mol wt, 236. Found: C, 61.02; H, 3.74; N, 35.70; mol wt, 229.

The ultraviolet spectrum (ethanol) shows  $\lambda_{max}$  290 m $\mu$  (sh) ( $\epsilon$  16,700), 282 m $\mu$  ( $\epsilon$  17,500), and 245 m $\mu$  (sh) ( $\epsilon$  8350).

The product on heating to 200° in air evolved a gas with concomitant formation of a higher melting solid, presumed to be dibenzo-1,3a,6,6a-tetraazapentalene (see below).

**Reaction of Bibenzotriazoles with Lithium Aluminum Hydride.** To a suspension of 1.50 g (0.04 mole) of lithium aluminum hydride in 100 ml of tetrahydrofuran was added a solution of 2.36 g (0.01 mole) of 1,2'-bibenzotriazole in 200 ml of tetrahydrofuran. The mixture was refluxed for 4 hr. After cooling, aqueous tetrahydrofuran was added to destroy unreacted hydride, and then the mixture was diluted with water and extracted with methylene chloride. The methylene chloride extracts were dried and evaporated, and the brown residue was treated with ether. The ether extract was filtered and evaporated, giving 1.3 g of brown crystals having an infrared spectrum nearly identical with that of benzotriazole. Recrystallization from water gave pure benzotriazole, identified by melting point and mixture melting point.

When 1,1'-bibenzotriazole was treated with lithium aluminum hydride as above, only starting material was recovered.

**Reaction of 1,1'-Bibenzotriazole with Dimethyl Sulfate. a. Mono-N-alkylation.** A mixture of 5.0 g (0.021 mole) of 1,1'-bibenzotriazole and 50 ml of purified dimethyl sulfate was stirred at 95° for 20 min. The unreacted starting material (1.0 g) was removed by filtration, and the filtrate was diluted to 300 ml with anhydrous ether. The colorless crystals which precipitated were washed with ether and air dried, weight 4.40 g (72% based on un-

ered starting material). Elemental analysis indicated that product contained 18% of the di-N-alkylation product described.

*d.* Calcd for 82%  $C_{14}H_{14}N_6SO_4$  + 18%  $C_{12}H_{20}N_6S_2O_8$ : C, 31.13; H, 3.93; N, 22.10; S, 9.62. Found: C, 45.16; H, 21.55; S, 9.64.

monoalkylation product 10, mp 180° dec, is very water soluble and is stable to light and air.

**Di-N-alkylation.** A mixture of 5.0 g (0.021 mole) of 1,1'-bistriazole and 50 ml of purified dimethyl sulfate was stirred at 110° for 2 hr, followed by cooling to room temperature during the night. The colorless crystals were collected on a filter, washed with ether, and dried over phosphorus pentoxide at room temperature. The product 6 (8.95 g, 86%) melted at 192–194° dec.

*d.* Calcd for  $C_{12}H_{20}N_6S_2O_8$ : C, 39.34; H, 4.13; N, 17.21; S, 13; mol wt, 163. Found: C, 38.96; H, 4.06; N, 17.51; S, 12; mol wt, 170, 179.

dialkylation product 11 is very water soluble and is stable to light and air.

A solution of 3.0 g of the above dialkylation product was added to 17 ml of saturated aqueous sodium iodide solution. Red crystals precipitated immediately, and the mixture was stirred in the dark for 15 min. The crystals were then collected on a filter in the dark and washed with water. After drying, the diiodide weighed 1.70 g.

*d.* Calcd for  $C_{14}H_{14}N_6I_2$ : C, 32.33; H, 2.71; N, 16.16; I, 47.45. Found: C, 32.44; H, 2.72; N, 16.12; I, 47.45.

The diiodide turns brown on exposure to light and forms a dark standing at room temperature for several weeks, even in the dark.

**Composition of Dialkylation Product 11 with Base.** To 20 ml of 10% sodium hydroxide at room temperature was added 2.0 g (0.0041 mole) of the dialkylation product, giving a bright yellow mixture which rapidly changed to a nearly colorless mixture. The small amount of oil which formed slowly crystallized. The mixture was extracted with ether, and the ether extracts were dried and evaporated to give 0.55 g of nearly colorless crystals, mp 61.5–63.5°. Recrystallization from cyclohexane gave pure 1-methylbenzotriazole (12), mp 64.5–65.5°, identified by melting point and comparison of its infrared spectrum with that of an authentic sample.<sup>18</sup>

**Reaction of 11 with Lithium Aluminum Hydride.** A slurry of 0.026 mole of lithium aluminum hydride in 125 ml of ether was stirred under nitrogen at room temperature while 3.0 g (0.006 mole) of the dialkylation product 11 was added. The light purple

suspension which resulted was treated with an additional 0.65 g of lithium aluminum hydride during 6 hr, and the mixture was then allowed to stand overnight. Excess hydride was destroyed with ethyl acetate and water, then 80 ml of 10% sodium hydroxide was added, the solid was removed by filtration, and the filtrate was extracted three times with ether. The combined ether extracts were dried over sodium sulfate, and the solvent was removed, giving 1.58 g (97%) of light brown crystalline solid, mp 59–61°, the infrared spectrum of which was identical with that of 1-methylbenzotriazole. Recrystallization gave pure 1-methylbenzotriazole, mp 63–64°.

**Reduction of 1,1'-Bibenzotriazole (4a).** Aluminum amalgam was prepared by immersing 0.57 g (0.02 g-atom) of aluminum foil (0.001 in.) in 5% aqueous mercuric chloride at room temperature for 1.5 min. The foil was rapidly washed with water and added immediately to a suspension of 5.0 g (0.021 mole) of 1,1'-bibenzotriazole in 500 ml of moist ether. The mixture was refluxed for 3 hr, at which time all of the amalgam had been consumed. The ether layer was decanted and evaporated under a stream of nitrogen until nearly all of the unreacted starting material (1.50 g) had precipitated. The benzotriazole was removed by filtration, and the filtrate was evaporated further, giving 2.7 g of brown crystals, mp 82–89°, having an infrared spectrum nearly identical with that of benzotriazole. The yield of crude product based on unrecovered starting material was 77%. Recrystallization from benzene gave pure benzotriazole (55%), identified by melting point, mixture melting point, and comparison of its infrared spectrum with that of an authentic sample.

**Thermolysis of 1,1'-Bibenzotriazole.** A solution of 2.0 g (0.0085 mole) of 1,1'-bibenzotriazole in 25 ml of di-*n*-butyl phthalate was heated under nitrogen at 250° for 30 min. The dark mixture was cooled to room temperature, and the precipitate was collected on a filter, washed with pentane, and air dried. There was obtained 0.95 g (54%) of dibenzo-1,3a,4,6a-tetraazapentalene (1), mp and mmp 237–238° with an authentic sample.

**Thermolysis of 1,2'-Bibenzotriazole.** A solution of 0.50 g (0.0021 mole) of 1,2'-bibenzotriazole in 3.7 g of di-*n*-butyl phthalate was heated at 250° for 25 min, by which time nitrogen evolution had nearly ceased. The dark solution was cooled under nitrogen, 7 ml of petroleum ether was added, and the precipitated, feathery crystals were collected on a filter and dried. The product (0.30 g, mp 248°) was recrystallized from methylene chloride-petroleum ether, giving 0.11 g of nearly colorless crystals, mp 255°. The mixture melting point with an authentic sample of dibenzo-1,3a,6,6a-tetraazapentalene (2) was undepressed.

# Tetrahexylammonium Benzoate, a Liquid Salt at 25°, a Solvent for Kinetics or Electrochemistry<sup>1</sup>

C. Gardner Swain, Atsuyoshi Ohno, David K. Roe, Ronald Brown, and Thomas Maugh, II

Contribution from the Department of Chemistry and the Laboratory for Nuclear Science, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139. Received November 17, 1966

**Abstract:** Tetrahexylammonium benzoate (THAB) is a liquid salt at 25°, miscible with most organic solvents but not with water. Its "solvent ionizing power"  $Y$ , based on rate of solvolysis of *t*-butyl chloride in THAB as solvent, is  $-0.39$ , intermediate between ethanol and water. Its ability to dissolve organic compounds, intrinsic conductance, and electrochemical inertness over a wide voltage range make it a suitable solvent for electrochemical studies. Half-wave potentials with a dropping mercury electrode in THAB are recorded for oxygen, fumaric acid, benzophenone, anthracene, and  $\beta$ -naphthol.

**T**etra-*n*-hexylammonium benzoate (hereafter THAB) is a viscous liquid at 25°, miscible with benzene, toluene, or carbon tetrachloride, in contrast to tetrapentylammonium or tetrabutylammonium benzoate, which are solids, only slightly soluble in benzene. As a liquid salt, it constitutes an unusual kind of solvent for kinetics or electrochemistry. Its synthesis and properties are described in the Experimental Section.

**Kinetics.** Reactions in fused salts are receiving increasing attention.<sup>2</sup> THAB permits such studies at 25° or below. To determine whether THAB is better regarded as a polar solvent because of its ionic bonds or as a nonpolar solvent because most of its bulk consists of saturated alkyl groups which shield and sterically hinder approach to the ionic centers, we measured its solvent polarity  $Y$ .  $Y$  values are defined operationally<sup>3</sup> as  $\log(k/k^\circ)$ , where  $k$  and  $k^\circ$  are first-order rate constants for solvolysis of *t*-butyl chloride at 25° in any solvent and in the standard solvent, ethanol-water (80:20), respectively. From the measured rate constant of  $3.8 \pm 0.2 \times 10^{-6} \text{ sec}^{-1}$ , in THAB as solvent, its  $Y$  value is  $-0.39$ , of the same order as that for 80% ethanol, *i.e.*, fairly polar, more polar than ethanol ( $-2.03$ ), but less polar than water ( $+3.49$ ). Its remarkable balance of ionic and nonpolar characteristics thus permits a moderate rate of solvolysis of *t*-butyl chloride, easily measurable by conventional kinetic techniques.

**Electrochemistry.** Solubility and reduction potential are two important properties of tetra-*n*-alkylammonium salts when used as supporting electrolytes in electrochemical studies. Of the many available salts in the series, tetrabutylammonium perchlorate has gained wide acceptance because of its solubility in a wide variety of solvents and because it is not easily reduced, *e.g.*, in aqueous solutions not before  $-2.6 \text{ v}$  vs. the saturated calomel electrode. No significant increase in

usable potential range results from further increases in alkyl chain length.

Current-voltage curves were obtained in THAB as solvent using both a dropping mercury electrode and a platinum microelectrode. Figures 1 and 2 illustrate typical results. Details are given in the Experimental Section. Relative to the silver chloride electrode, oxygen, fumaric acid, benzophenone, anthracene, and  $\beta$ -naphthol exhibited  $E_{1/2}$  values at  $-0.37$ ,  $-0.50$ ,  $-1.42$ ,  $-1.7$ , and  $-2.3 \text{ v}$  with the dropping mercury electrode. Thus, THAB is usable as a solvent and advantageous because it is a good solvent for organic compounds, has adequate intrinsic conductance, and ions that are electrochemically inert over a wide range.

## Experimental Section

**Synthesis.** Tetrahexylammonium iodide (Eastman White Label) was recrystallized three times from 3:1 acetone-ether solutions, mp  $104\text{--}105^\circ$ , or in later work used without purification without adverse effects. Freshly precipitated silver oxide (0.15 mole) was added in several portions with prolonged shaking to a solution of 25 g (0.052 mole) of the iodide in 150 ml of methanol-water (80:20). The residual iodide ion was negligible. Without isolation of the tetrahexylammonium hydroxide, the filtered solution was neutralized with reagent benzoic acid dissolved in 80% methanol to pH 7, using "pHydron" pH 7-8 paper as an indicator. The volume of benzoic acid solution required agreed with that calculated. Solvent was evaporated at or below 25° in a rotary evaporator at  $10^{-1}$  to  $10^{-2} \text{ mm}$ . The pale yellow oil obtained was dried in a vacuum desiccator under reduced pressure over  $\text{P}_2\text{O}_5$  or  $\text{Mg}(\text{ClO}_4)_2$  for a day; yield 20 g. Last traces of water are difficult to remove. Its analysis corresponds to a hemihydrate. *Anal.* Calcd for  $\text{C}_{24}\text{H}_{51}\text{NO}_2$ : C, 78.25; H, 12.08; N, 2.94. Calcd for  $\text{C}_{24}\text{H}_{51}\text{NO}_2 \cdot 0.5 \text{ H}_2\text{O}$ : C, 76.80; H, 12.06; N, 2.93. Found: C, 76.67; H, 11.84; N, 2.90. A sample heated for 10 min at  $100^\circ$  (25 mm) partially decomposed to a mixture analyzing 72.62% C and 11.94% H, indicating accumulation of benzoic acid. Further drying of another sample for 2 weeks at 25° (25 mm) over  $\text{Mg}(\text{ClO}_4)_2$  also gave some decomposition (75.09% C and 11.71% H).

An alternate, less desirable procedure for the conversion of iodide to hydroxide involved ion exchange. The iodide (2 g) in 80% methanol was charged into 130 ml of Dowex I-X4 anion-exchange resin in hydroxide form in a 20-mm i.d. column, followed by elution with 600 ml of 80% methanol at the rate of 20 drops/min. There may be a possibility of contamination of the THAB by traces of amines derived from the resin in this procedure.

**Properties.** At 25° THAB has a viscosity similar to that of glycerol and a density of 0.90 g/ml. It does not have a liquid crystal state. It solidifies at Dry Ice temperature. Specific resistance was 18 kohm cm after several days in a vacuum desiccator at 25-mm pressure over  $\text{Mg}(\text{ClO}_4)_2$ . Some water was probably absorbed upon

An aqueous [NaCl]/Ag electrode was used as a reference. Contact ded by a short piece of porous glass rod (Corning 7930). istics of the DME at 0 v were  $m = 6.10$  mg/sec,  $t = 5.62$

A short piece of platinum wire was used as the counter

The polarograph was a Heath EUW-401. Oxygen re- the THAB solvent was accomplished by a nitrogen purge. rements were made at room temperature,  $23 \pm 3^\circ$ . No was made for  $iR$  voltage drop in the cell. Although the ph is essentially a potentiostat, the potential is indef- current only if zero resistance exists between the refer- indicator electrodes. As noted above, THAB solutions ver high resistance and the cell used did not allow the two to be positioned close together.

Figure 2. Scan rate 100 mv/sec: curve A, residual cyclic volt-ammogram of platinum microelectrode; curve B, reduction of oxygen.

From curve A in Figure 1, the anodic limit with a mercury electrode is  $+0.2$  v (AgCl/Ag). The lack of an anodic wave at potentials negative to the reference suggests either that there is negligible iodide remaining in the salt or that mercurous(ic) iodide is soluble in THAB.

No significant concentrations of reducible impurities, including iodine, contributed to the cathodic current at potentials positive to  $-1.8$  v, but a reduction wave was evident beyond this point. After a perceptible diffusion plateau of  $80 \mu\text{A}$  at  $-2.5$  v, the current increased sharply. The last current rise is undoubtedly the reduction of THA ion and the impurity wave was probably an alkali metal cation since  $E_{1/2}$  was  $-2.09$  v. Sodium or potassium ions at 0.01 M are not uncommon in reagents of the quality used in this synthesis. It is also possible that hydrogen ion reduction from traces of water may have contributed to the reduction wave, although this is not reported to be the case with neutral, aqueous solutions of tetraalkylammonium salts.

The point of zero charge of the mercury electrode was  $-0.25$  v, based on observations of the shapes of the current-time curves of individual drops. The slope of the (peak) charging current-potential curve is very small so that the intersection on the potential axis (the point of zero charge) is difficult to determine. The change in shape of the charging current-time curves on either side of  $-0.25$  v was very evident, however. Drop times changed rather markedly with potential beyond  $-1.5$  v. At  $-1.7$  v, the decrease was about 30% compared to the drop time at 0 v.

Oxygen is reduced in a single wave having  $E_{1/2} = -0.37$  v. The diffusion current was  $3.4 \mu\text{A}$  after prolonged contact with the atmosphere (curve B). Since the difference between the potentials at one-fourth and three-fourths of the diffusion current was 75 mv, the rising part of the wave was not related to a simple diffusion-controlled process but instead was activation controlled. Traces of water were undoubtedly present, so that reduction of oxygen to hydroxide ion was possible.

Reduction waves (and  $E_{1/2}$  values) were observed for anthracene ( $-1.7$ ), benzophenone ( $-1.42$ ), fumaric acid ( $-0.50$ ), and  $\beta$ -naphthol ( $-2.3$ ). Curve C of Figure 1 shows a polarogram for anthracene added as a small crystal. In aqueous solution, anthracene is reduced at  $E_{1/2} = -2.4$  v. Interference from the assumed alkali metal cation reduction prevented an assessment of the quarter-wave potential difference. The reduction of naphthalene was not observable over the accessible range to  $-2.6$  v.

A platinum microelectrode in pure THAB exhibited an anodic limit at about  $+0.3$  v, and at  $-1.2$  v cathodic current became significant, as shown in Figure 2, curve A. Within this potential range, the current was essentially capacitive in that a first-power dependence on scan rate was observed. Oxygen reduction occurred as a drawn-out wave (curve B), rising from  $-0.2$  v to a peak at  $-0.7$  v when the scan rate was 100 mv/sec. The peak potential was very dependent upon scan rate. The addition of a small amount of water did not alter the residual curve, which suggests that traces of water were already present. A mixture of 25% by volume of toluene with THAB had essentially the same residual currents as the pure liquid.

# Evaluation of the Basicity of Phosphine Oxides and Phosphine Sulfides by Measurements of Chemical Shift in Sulfuric Acid Solutions<sup>1</sup>

Paul Haake,<sup>2a</sup> Robert D. Cook, and Gail H. Hurst<sup>2b</sup>

Contribution No. 2001 from the Department of Chemistry, University of California, Los Angeles, California 90024. Received October 18, 1966

**Abstract:** The  $pK_{BH^+}$  values of  $(CH_3)_3PO_2H$ ,  $CH_3P(O)(OCH_3)_2$ ,  $(C_6H_5)_2P(O)CH_3$ ,  $C_6H_5P(O)(CH_3)_2$ ,  $(C_6H_5)_2P(S)CH_3$ ,  $C_6H_5P(S)(CH_3)_2$ , and  $(CH_3)_2PS_2H$  have been determined by measurements of chemical shift of methyl groups bonded to phosphorus as a function of sulfuric acid concentration. The data indicate considerable  $\pi$  bonding in PS and PO bonds. Phosphine oxides are about  $10^6$  less basic than amine oxides, arsine oxides, and stibine oxides. Previous reports of the basicity of phosphine oxides are misleading. The method used here has been validated by study of acetophenone and N,N-dimethylacetamide;  $pK$ 's of these compounds are known from other methods.

There has been considerable interest in the nature of the P–O bond in phosphine oxides especially in regard to the role of d orbitals in  $\pi$  bonding.<sup>2</sup> Bond energies,<sup>4</sup> bond lengths,<sup>3,5</sup> infrared spectra,<sup>3,7</sup> C<sup>13</sup>–H coupling constants,<sup>8</sup> and hydrogen bonding<sup>9</sup> all indicate considerable P–O  $\pi$  bonding in phosphine oxides. The N–O bond in trimethylamine oxide, on the other hand, appears to be a single bond.<sup>3,8</sup>

There has been little work on the basicity of phosphine oxides and sulfides, and this might be expected to give indications concerning P–O and P–S bonding in both neutral and protonated forms. N Oxides are sufficiently basic to be measured by potentiometric titration; the  $pK_{BH^+}$ <sup>10</sup> of  $(CH_3)_3NO$  is 4.7.<sup>11</sup> The  $pK_{BH^+}$  of  $(CH_3)_3PO$  has been listed in a table as 0,<sup>11</sup> but this was on the basis of titration and evaluation of its effect on HBr-catalyzed hydrolysis of methyl acetate which indicated basicity immeasurably small by these techniques. This estimate for the basicity of  $(CH_3)_3PO$  has been quoted in a review on the base strength of weak organic bases.<sup>12</sup> By measurements of proton chemical shifts as a function of sulfuric acid concentrations, we had determined the basicity of a phosphinic acid,  $(CH_3)_2PO_2H$ , and a phosphinate ester,  $(C_6H_5)_2PO_2CH_3$ ,

in connection with a study of the acid-catalyzed hydrolysis of phosphinates.<sup>13</sup> We have now confirmed the validity of this method and studied a more complete set of compounds which may be classed as phosphine oxides and sulfides.

## Results

In the compounds studied, chemical shifts for CH<sub>3</sub> hydrogens were measured relative to  $(CH_3)_3N^+H$ ; a sample plot of the data for dimethylphenylphosphine oxide is shown in Figure 1. Trimethylammonium ion was used as a standard to minimize changes in chemical shifts due only to changes in solvation. The large solvation effects should be in the media with high  $[H_2SO_4]$  where most or all of the water will be involved in solvating protons. This would probably decrease solvation of the protonated phosphine oxide and lead to a change in chemical shift relative to an uncharged and/or unprotonated standard. By using  $(CH_3)_3N^+H$  as a standard we should minimize this problem, since both  $BH^+$  and  $(CH_3)_3N^+H$  have one acidic hydrogen for interaction with solvent and solvation effects should, therefore, be similar.

The data are plotted against the  $H_0$  scale<sup>14</sup> since this is a scale conveniently available as a standard. Although there are problems with the  $H_0$  scale based on primary anilines serving as a measure of acidity when studying other bases or substrates,<sup>15</sup> this can be considered by use of eq 1<sup>16</sup> where the  $M$  value is a measure

$$\log [BH^+]/[B] = M(pK_{BH^+} - H_0) \quad (1)$$

of the protonation behavior of B relative to Hammett bases (primary anilines).<sup>17</sup> If  $M = 1$ , B is a Hammett

(14) (a) L. P. Hammett, "Physical Organic Chemistry," McGraw-Hill Book Co., Inc., New York, N. Y., 1940, Chapter IX. (b) The scale used here is Hammett's with the corrections above 60%  $H_2SO_4$  given by M. J. Jorgenson and D. R. Hartter, *J. Am. Chem. Soc.*, **85**, 878 (1963). This scale is internally consistent since it is based on primary anilines and seems to be a reasonable one to adopt as a standard. It appears to be finding general acceptance; see, for example, K. Yates and H. Wai, *Can. J. Chem.*, **43**, 2131 (1965).

(15) We use eq 1 with  $M$  as a measure of the effect of medium relative to the effect on Hammett bases. Other forms of this equation have been used<sup>13,16</sup> with  $a$  rather than  $M$ , but use of  $M$  should lead to less confusion. Equation 1 is discussed in more detail in ref 13.

<sup>a</sup> Chemical shifts of underlined  $CH_3$  groups were measured. <sup>b</sup> This is equal to  $pK$ ; from sigmoid graph of  $\Delta$  against  $H_0$ . <sup>c</sup> The values in parentheses are intercepts (and their standard deviations) determined by least squares. <sup>d</sup> Values of chemical shifts are relative to  $(CH_3)_3N^+H$ ; positive indicates upfield shift. <sup>e</sup> This is number of points used to determine  $M$  and  $pK_{BH^+}$  by least squares on eq 2. More data were obtained and used to get  $H_0$  at half-protonation,  $\Delta_B$ , and  $\Delta_{BH^+}$ .

base.<sup>13</sup> All the data we obtained could be plotted according to eq 1 and gave straight lines, from which  $M$  and  $pK_{BH^+}$  values could be obtained:  $M = \text{slope}$ ,  $pK_{BH^+} = \text{intercept}/M$ .

A, R = R' =  $CH_3$ ; R'' = OH E, R = R' =  $C_6H_5$ ; R'' =  $CH_3$   
 B, R =  $CH_3$ ; R' = R'' =  $OCH_3$  F, R =  $C_6H_5$ ; R' = R'' =  $CH_3$   
 C, R = R' =  $C_6H_5$ ; R'' =  $CH_3$  G, R = R' =  $CH_3$ ; R'' = SH  
 D, R =  $C_6H_5$ ; R' = R'' =  $CH_3$

The  $pK_a$ 's can also be obtained by evaluation of the point where  $[BH^+] = [B]$ . This is the halfway point on the sigmoid curves (e.g., Figure 1), i.e., the point where  $\Delta = (\Delta_B + \Delta_{BH^+})/2$ . Table I gives all our data for phosphine oxides including  $pK$ 's determined by this method and  $pK$  and  $M$  values from a least-squares calculation using eq 1. The chemical shifts found for B and  $BH^+$  relative to  $(CH_3)_3N^+H$  are also given in Table I. It can be seen that  $(\Delta_B - \Delta_{BH^+})$  is large enough to give reliable results. Determination of  $pK$ 's by either method depends on the values of these chemical shifts, but it turns out that application of eq 1 to determination of  $pK$ 's is not as sensitive to slope as one might expect from the fact that the  $pK$  is determined by the intercept. Since a lowering of slope lowers the absolute value of the intercept (the intercepts in these plots are negative), there is a compensating effect since  $pK = \text{intercept}/\text{slope}$ . Consequently, although some standard deviations are large in Table I, the  $pK_{BH^+}$  values from eq 1 and from half-protonation agree well. The larger standard deviations come from those compounds where only a few points were obtained between 5 and 95% protonation due to a steep dependence of protonation on  $H_0$ , which results in a high  $M$  value.

Another argument for standard use of the  $H_0$  scale in studies of basicity relates to the  $M$  values. It seems

likely that these  $M$  values may be quite useful in evaluation of solvation effects on the protonation of weak bases when there is a large enough body of these data available.

Figure 1. Dependence of chemical shift of methyl groups of dimethylphenylphosphine oxide and dimethyldithiophosphinic acid on  $H_0$  in aqueous sulfuric acid.

Perhaps the most important question in this study has to do with the reliability of this method. Despite the use of  $(CH_3)_3N^+H$  as a standard it could be argued that all the data observed here could be largely medium effects so that the apparent titration curves observed (e.g., Figure 1) could have little relation to basicity. We have several pieces of evidence which refute this line of devil's advocacy. First, we used this method to determine the  $pK$  values for  $N,N$ -dimethylacetamide (H) and acetophenone (I); the chemical shifts of the

<sup>a</sup> By least squares using  $\log ([BH^+]/[B]) = M(pK - H_0)$ . Values in parentheses under  $pK_{BH}^{+}$  are the values of the intercepts and their standard deviations as determined by least squares. The  $\pm$  values under  $M$  are standard deviations of the slope by the same method.

<sup>b</sup> Chemical shift in cps from the methyl hydrogens of  $(CH_3)_3N^+H$ . <sup>c</sup> Reference 12. <sup>d</sup> K. Yates and H. Wai, *Can. J. Chem.*, **43**, 2131 (1965).

underlined methyl groups were evaluated as a function of acidity. The  $pK_{BH}^{+}$  values obtained by the nmr method are in good agreement with those previously observed (Table II). Secondly, dimethyl sulfone is known to be very weakly basic and is only partially protonated in concentrated sulfuric acid.<sup>12,19</sup> We observe no titration curve of chemical shifts for dimethyl sulfone in the region of acidity where titration curves are observed for the compounds in Table I. Finally, we have studied trimethylamine oxide (J) by this method. This amine oxide has a  $pK$  in the range

measurable by potentiometric methods:  $pK_{BH}^{+} = 4.65$ .<sup>11</sup> We find less than 3-cps change in chemical shift between  $H_0 = 0$  and  $H_0 = -7$  for this compound. Since protonation of J is essentially complete throughout this range, this result further supports the validity of our method.

Two  $pK$  values are listed in Table I for dimethyldithiophosphinic acid,  $(CH_3)_2PS_2H$ . The titration curve for this compound is shown in Figure 1; two inflections are clearly present. These are probably due to: (1) protonation of the anion,  $H^+ + Me_2PS_2^- \rightleftharpoons Me_2PS_2H$ ,  $pK_{AH} = -1.07$ ; (2) protonation of the acid,  $H^+ + Me_2PS_2H \rightleftharpoons (CH_3)_2PS_2H^+$ ,  $pK_{BH}^{+} = -5.72$ . The  $pK_{AH}$  is inconsistent with the results of Kabachnik, *et al.*,<sup>20</sup> on other dithiophosphinic acids. The  $pK_{AH}$  values they found by potentiometric titration might be in error due to problems with false  $pK$ 's of strong acids.<sup>21</sup> Alternatively, the two inflection points we observed here could be due to (1) protonation of the neutral acid and (2) another phenomenon. Since  $(CH_3)_2PO_2H$  is about 1 to 2 powers of 10 less basic than phosphine oxides and phosphine sulfides have  $pK_{BH}^{+} = -4.5$ , it does seem very likely that  $pK_{BH}^{+}$  is  $-5.6$  for  $(CH_3)_2PS_2H$ . It then is difficult to attribute  $pK = -1.1$  to anything other than  $(CH_3)_2PS_2H \rightleftharpoons (CH_3)_2PS_2^- + H^+$ .

## Discussion

**Basicity of Phosphine Oxides.** The  $pK_{BH}^{+}$  of trimethylphosphine oxide was reported<sup>11,12</sup> as 0; on the basis of our results (Table I), it seems likely that this is in error. Certainly phosphine oxides (K) are generally protonated (eq 2) to only a small extent in 1  $M$  acid.

The basicities we have measured for phosphine oxides are compared with other oxides in Table III. Therefore, in basicity phosphine oxides resemble carbonyl

Table III. Comparison of Basicities of Some Oxides

Compound	$pK_{BH}^{+}$
$CH_3CO(C_6H_5)_2$	-6.5 <sup>a,b</sup>
$(CH_3)_3NO$	4.7 <sup>c</sup>
$(CH_3)_2P(O)C_6H_5$	-2.4 <sup>b</sup>
$CH_3P(O)(C_6H_5)_2$	-3.2 <sup>b</sup>
$(CH_3)_3AsO$	3.8 <sup>c</sup>
$(CH_3)_3SbO$	5.4 <sup>c</sup>

<sup>a</sup> Footnote d, Table II. <sup>b</sup> This work. <sup>c</sup> Reference 11.

compounds more than the oxides of other group Va elements; the oxides of nitrogen, arsenic, and antimony are  $10^4$ – $10^8$  times more basic than phosphine oxides. Amine oxides can have no N–O  $\pi$  bonding, and carbonyl groups are known to have considerable double bond character.

Although C and D do not have  $C_{3v}$  symmetry, it is probable that these phosphine oxides have two nearly equivalent  $\pi$  orbitals<sup>22,23</sup> so that K might be better written as  $\text{>P}^+=\text{O}$ . The short P=O bond length<sup>4</sup> and the radial density distributions of the phosphorus and oxygen orbitals probably contribute to the strength of  $\pi$  bonding in K.<sup>25</sup> The longer As–O and Sb–O bonds would cause weaker  $\pi$  bonding in arsine and stibine oxides.

(22) The interaction of the phenyl substituents with the P–O  $\pi$  system is probably small since there is little difference in the length of  $C(sp^2)$ –P and  $C(sp^3)$ –P bonds.<sup>24</sup> Therefore, in C and D there should be little perturbation of a symmetrical  $\pi$ (P–O) system with two  $\pi$  orbitals.

(23) In  $(CH_3)_3PO$ ,  $r(P-C) = 1.81 \text{ \AA}$ ;<sup>4</sup> in  $(C_6H_5)_3PO_2H$ ,  $r(P-C) = 1.81 \text{ \AA}$ .<sup>24</sup>

(24) T-T. Liang and K-C. Chi, *Acta Chim. Sinica*, **31** (2), 155 (1965).

(25) Related discussions of d–p  $\pi$  bonding: D. W. J. Cruickshank, *J. Chem. Soc.*, 5846 (1961); D. P. Craig, A. Maccoll, R. S. Nyholm, L. E. Orgel, and L. E. Sutton, *ibid.*, 332 (1954). The simple view of  $\pi$  bonding in K and L would involve d–p, P–O overlap. However, to mention two possible perturbations, there might be mixing of phosphorus orbitals resulting in stronger  $\pi$  and/or  $\sigma$  bonds and  $\pi$  bonding involving hybrid oxygen orbitals, such as  $sp^2$ , would be possible.

here have been no structural reports on a protonated or alkylated phosphine oxide, but the structures of aryl phosphate esters are known and indicate  $\nu(\text{P}-\text{O}) \sim 1.55 \text{ \AA}$  and  $\angle(\text{P}-\text{O}-\text{R}) \sim 120^\circ$ .<sup>26</sup> Using  $e$  parameters, a reasonable model for the structure would involve an  $sp^2$  oxygen atom. It is impossible to intuitively predict exactly what oxygen orbitals are involved in  $\pi$  bonding in L, but it is clear that the shorter P-OR bond length and the use of some oxygen orbital character in  $\sigma$  bonding should lead to a reduction in P=O  $\pi$  bonding.<sup>25</sup> In addition, the presence of a large on L and the consequent orbital contractions might be detrimental to strong  $\pi$  bonding.

The large bond energies of P-O bonds in  $(\text{CH}_3)_3\text{PO}$  ( $\text{C}_6\text{H}_5)_3\text{PO}$  (139 and 128 kcal/mole, respectively)<sup>4</sup> are consistent with strong  $\pi$  bonding in K. The bond length of the P-O bonds of  $(\text{CH}_3\text{O})_3\text{P}$  (91 kcal/mole)<sup>4</sup> indicates the kind of decrease which might be expected on protonation.

Therefore, although many factors can affect  $pK$ 's, judging stability of both acid and basic forms, solvation effects, etc., the large differences in basicity shown in Table III and consideration of bonding and bond energies certainly suggest that  $\pi$  bonding in phosphine oxides makes an important contribution to the structure. On the other hand, it appears that  $\pi$  bonding is quite weak in arsine and stibine oxides.

Substitution of  $\text{CH}_3\text{O}$  or  $\text{HO}$  for  $\text{C}_6\text{H}_5$  in phosphine oxides reduces the basicity considerably (Table I). It thus appears that the inductive effect of the  $\text{CH}_3\text{O}$

$\text{HO}$  groups are predominant over resonance effects. In A and B there is probably a more complex  $\pi$  system than in C and D, but resonance effects might be quite different from carboxylates and other systems involving only p orbitals. We assume that in A and B, protonation is on the P=O oxygen, but protonation on a P-OR oxygen has not been excluded.

**Phosphine Sulfides.** The difference of basicity of  $(\text{CH}_3)_3\text{S}$  ( $pK_{\text{BH}^+} = -3.8$ ) and  $(\text{CH}_3)_3\text{P}$  ( $pK_{\text{BH}^+} = 4$ )<sup>12</sup> indicates that the differences between phosphine oxides and phosphine sulfides in Table I are due largely to the substitution of sulfur for oxygen. Therefore,  $\pi$  bonding must also be important. However, Pearson has concluded there is less P-S than P-O  $\pi$  bonding,<sup>28</sup> and our basicity data are only suggestive. Further data related to P-S  $\pi$  bonding are needed.

**$M$  Values.** The  $M$  values for phosphine oxides are less than 1 by a considerable amount, indicating that these bases are not behaving as Hammett bases. Using symbols  $B'$  for Hammett base and  $B$  for the bases in this study:<sup>12</sup>

$$\log f_B/f_{B'H} \cdot f_{BH} \cdot f_{B'} = (1 - M)(H_0 - pK_{\text{BH}^+}) \quad (3)$$

We have previously<sup>12</sup> discussed the relation of a low  $M$  value to acid-inhibited hydrolysis of  $p$ -nitrophenyl phenylphosphinate and proposed that an important factor was a decrease in  $f_B$  with increasing acidity.<sup>27</sup> The tendency of phosphine oxides to form hydrogen bonds may be an important factor in this effect, and the  $M$  values (Table I) can be explained in this framework. The important interaction of a neutral base with sulfuric acid solvent should be by hydrogen bonding. Oxygen should normally form stronger hydrogen

bonds than nitrogen and nitrogen stronger than sulfur. Since the Hammett bases are anilines, the oxygen base should be salted in more strongly and  $f_B/f_{B'}$  should decrease for phosphine oxides as acid concentration increases. The sulfur bases should be salted in less strongly than anilines and  $f_B/f_{B'}$  should increase with increasing acid concentration. Both of these effects would explain the  $M$  values observed. This hypothesis also explains the  $M$  values for  $(\text{CH}_3)_3\text{PO}_2\text{H}$  and  $(\text{CH}_3)_3\text{PS}_2\text{H}$  compared to the other phosphine oxides and phosphine sulfides. These bases have two oxygens or sulfurs which can form hydrogen bonds and therefore ought to show lower  $M$  values than  $(\text{CH}_3)_3\text{P}(\text{O})\text{C}_6\text{H}_5$  and  $(\text{CH}_3)_3\text{P}(\text{S})\text{C}_6\text{H}_5$ , as they do.

## Experimental Section

Melting points were taken with a calibrated Mel-Temp block. Analyses were performed by Miss Heather King, UCLA micro-analytical laboratory. Nuclear magnetic resonance spectra were taken on a Varian Model A-60 instrument; tetramethylsilane was used as a standard. Infrared spectra were taken on a Perkin-Elmer Model 421 spectrophotometer.

**Diphenylmethylphosphine Oxide.** The oxide was prepared from diphenylmethylphosphine by oxidation with oxygen. The phosphine was prepared from diphenylchlorophosphine (Columbia Chemical Co.) in ether by addition of methylolithium in ether (Alfa Inorganics Inc.), followed by distillation. The oxide was recrystallized from benzene, mp  $109-110^\circ$  (lit.<sup>29</sup> mp  $110-111^\circ$ ). The infrared spectrum in KBr included absorptions at  $1430$  (aromatic) and  $1293 \text{ cm}^{-1}$  (P=O). The nmr spectrum shows a doublet at  $\tau$  8.0 with  $J_{\text{PC}} = 13$  cps and two multiplets with centers at  $\tau$  2.2 and 2.5 integrating as expected.

Anal. Calcd for  $\text{C}_{16}\text{H}_{15}\text{PO}$ : C, 72.21; H, 6.06. Found: C, 72.30; H, 6.24.

**Dimethylphenylphosphine Oxide.** This oxide was prepared by oxidation of the corresponding phosphine with oxygen. The phosphine was prepared from phenyldichlorophosphine (Victor Chemical Co.) and methylolithium and purified by distillation. The oxide is very hygroscopic and when very dry melts at  $115-119^\circ$  (lit.<sup>29</sup>  $107-110^\circ$ ). The infrared spectrum shows absorption at  $1430$  and  $1410 \text{ cm}^{-1}$  (aromatic) and  $1285 \text{ cm}^{-1}$  (P=O). The nmr spectrum in  $\text{CDCl}_3$  exhibits a doublet at  $\tau$  8.22 with  $J_{\text{PC}} = 13$  cps and multiplets at  $\tau$  2.47 and 2.2 integrating as expected.

**Dimethyl Methylphosphonate.** This ester was prepared by treating trimethyl phosphite with methyl iodide. The ester was distilled at  $84-89^\circ$  ( $34-35 \text{ mm}$ ) [lit.<sup>30</sup>  $71^\circ$  ( $13 \text{ mm}$ )]. The infrared spectrum shows absorptions at  $1245 \text{ cm}^{-1}$  (P=O) and  $1030$  and  $1055 \text{ cm}^{-1}$  (POC) as well as  $1182 \text{ cm}^{-1}$ . The nmr shows a doublet at  $\tau$  8.55 (area = 1) with  $J_{\text{PC}} = 17$  cps and a doublet at  $\tau$  6.33 with  $J_{\text{PC}} = 11$  cps; integrations were in the expected ratio.

**Diphenylmethylphosphine Sulfide.** This sulfide was prepared by refluxing diphenylchlorophosphine and sulfur in  $\text{CS}_2$  overnight.<sup>31</sup> The solvent was removed, ether added, and an equimolar amount of methylolithium added to the solution. The sulfide distilled at  $183-185^\circ$  ( $2 \text{ mm}$ ) [lit.<sup>31</sup>  $181^\circ$  ( $1.5 \text{ mm}$ )]. The infrared spectrum shows bands at  $1410$ ,  $1434$ , and  $1478 \text{ cm}^{-1}$  (aromatic) and at  $619$  and  $608 \text{ cm}^{-1}$  (P=S).<sup>32</sup> The nmr spectrum shows a doublet at  $\tau$  7.82 with  $J_{\text{PC}} = 12$  cps and multiplets centered at  $\tau$  2.25 and 2.7 with the expected integration.

**Dimethylphenylphosphine Sulfide.** The corresponding phosphine was treated with sulfur in ethereal solution, the solvent evaporated off, and the product, dimethylphenylphosphine sulfide, was recrystallized from hot water, mp  $42-43^\circ$  (lit.<sup>31</sup> mp  $42^\circ$ ). The infrared spectrum includes bands at  $1431$ ,  $1405$ , and  $1413 \text{ cm}^{-1}$  (aromatic) and at  $585 \text{ cm}^{-1}$  (P=S).<sup>32</sup> The nmr spectrum shows a

**Measurement of  $pK$ 's.** The solutions were made up as previously described<sup>13</sup> at a concentration of  $\sim 10^{-1} M$  for both standard and substrate.

Chemical shifts ( $\Delta$ ) were plotted against  $H_0$  (Figure 1) to give approximate  $pK$  and  $M$  values according to eq 2. The approximate  $pK$  can be obtained from the  $H_0$  value at  $1/2(\Delta_B - \Delta_{BH^+})$ . The approximate  $M$  value can be obtained graphically or by solution of eq 2 at some point other than  $H_0 = pK_{BH^+}$ . Values of  $\Delta_B$  and  $\Delta_{BH^+}$  were then obtained from the smoothed curve of  $\Delta$  vs.  $H_0$ :  $\Delta_B$  is the  $\Delta$  at  $H_0$  (0.5% protonation) =  $pK_{BH^+} - 2.3/M$ ,  $\Delta_{BH^+}$  is the  $\Delta$  at  $H_0$  (99.5% protonation) =  $pK_{BH^+} + 2.3/M$ . A least-squares analysis of the data was then done using eq 2 and points between 5 and 95% protonation, i.e., between  $H_0 = pK \pm (1.3/M)$ .

**Acknowledgment.** The nmr spectrometer used in this work was purchased with funds from the National Science Foundation. Sigma R. Alpha prepared the dimethyl methylphosphonate.

## Comparison of Liquid-Phase and Gas-Phase Reactions of Free Radicals<sup>1</sup>

Frank R. Mayo

Contribution from the Stanford Research Institute, Menlo Park, California 94025.  
Received October 19, 1966

**Abstract:** The theoretical and practical effects of gas–liquid phase change on rates and products of free radical reactions are discussed, mostly in terms of ratios of rate constant for competing reactions. Effects of free volumes, concentration changes, solvent cages, and third bodies are now fairly well understood, but when enough competing reactions are involved, the effect of phase change may become complicated. Previous work provides several examples where phase change has, or has not, affected competing free radical reactions and several instances where solvent change has affected competitions. The present survey now suggests that solvation effects are widespread in free radical reactions but often obscured by the necessity of studying them in competing reactions. Solvation effects in the most inert solvents appear to be as far from gas-phase results as they are from solvation effects in the most polar solvents. Thus, comparisons of gas-phase and liquid-phase reactions of free radicals are important in any absolute measure of solvation effects.

During the development of free radical chemistry, the organic and polymer chemists have been concerned mostly with liquid-phase reactions, while physical chemists have been concerned mostly with gas-phase reactions. There has been little effort to correlate the work of the two groups. As considerable data have accumulated on each phase, with little overlap, several related questions arise. To what extent can we predict rates or products in one phase from data in the other? Is there any discernible change in rate constants with phase change? Why do some reactions proceed in both phases while others proceed only in one? Which phase should be chosen for preparative purposes? The object of this paper is to consider some reactions for which data on both phases are available, to deduce some generalizations, and to point out remaining problems. The next two portions of this section consider some theoretical aspects of phase changes, then some generalities about free radical reactions. The following section then reviews experimental data. Conclusions are summarized in the last section.

(1) This paper extends one presented to the Division of Organic Chemistry at the Symposium on Reactions of Free Radicals at the 149th National Meeting of the American Chemical Society, Detroit, Mich., April 7, 1965, and subsequently to the Colorado, California, and Santa Clara Valley Sections.

**Theoretical Aspects of Phase Changes.** One interesting aspect of phase change is the free-volume effect. When we assume that the activities of the reactants and the activated complex are measured by their vapor pressures and that attractive forces with other molecules are negligible, the partial pressure of each reactant is given by

$$p(v - b) = nRT$$

Here  $v - b$  is the corrected volume in the van der Waals equation, corresponding roughly to the free volume of the container not occupied by molecules. When we go from (say) 0.01  $M$  reactant in the gas phase to a 0.01  $M$  solution in benzene at 50°,  $v - b$  changes from about 999.7 ml/l. to about 250 ml/l. (assuming that there is no free volume in benzene at 0°K) and the vapor pressure of the reactant, in the absence of all interactions with the solvent, is increased fourfold. We neither find nor expect phase change to have much effect on rates of first-order reactions: although the vapor pressure of the reactant (in the liquid phase) is four times as great, the reactant is present in only one-fourth of the volume. However, for a second-order reaction, the product of the vapor pressures of the reactants is increased 16-fold while the volume is decreased only fourfold, and the

reaction per unit volume should be four times as  
For a third-order reaction, the factor should be

re elegant treatments come to similar conclusions.  
n<sup>2a</sup> concludes that a reaction will go fastest in the  
m which favors the association of reactants and  
tes that a bimolecular reaction might be 20 times  
in solution as in the gas phase. The collision  
of reaction rates suggests that there should be  
three times as many collisions between a pair  
of molecules in solution as in the gas phase  
at, for the same activation energy, the rate will be  
proportionally higher.<sup>3</sup> The absolute rate theory,  
considerations of entropies of activation, leads  
same final result.<sup>3</sup>

low pressures, the rates of some gas-phase reac-  
become smaller than expected from rates at higher  
pressures or in the liquid phase. In unimolecular  
reactions, first-order rate constants begin to fall off at  
pressures which are insufficient to maintain an equi-  
librium concentration of activated reactant molecules.  
At pressures range roughly from a fraction of a  
centimeter of mercury for molecules with 6 or more  
atoms to some hundreds of millimeters for molecules  
with fewer atoms.<sup>2c</sup> In combinations of two atoms  
or small free radicals, the heat of reaction is sufficient  
to cause immediate separation unless some of this heat  
is removed by collision with a third body. Thus,  
reactions of atoms normally require a third body  
(molecular) but bimolecular reactions of radicals  
are less dependent on pressure as the complexity of  
the radicals and the opportunities for internal dissipa-  
tion of the heat of reaction increase.<sup>2d</sup>

Now we examine data on rates of free radical reac-  
tions and since the transition-state theory treats a rate  
equilibrium, let us see what phase change does  
to the rate. Table I gives the equilibrium constants for  
the dissociation of N<sub>2</sub>O<sub>4</sub> in the gas phase and in several  
liquids.<sup>4</sup>

Equilibrium Constants<sup>4</sup> for N<sub>2</sub>O<sub>4</sub>  $\rightleftharpoons$  2NO<sub>2</sub> at 20°

Solvent	K, M	$\Delta H_0^\circ$ , <sup>a</sup> kcal/mole
Gas phase	382	13.7
SiCl <sub>4</sub>	17.8	20.5
CS <sub>2</sub>	13.3	19.4
CCl <sub>4</sub>	8.05	18.8
CHCl <sub>3</sub>	5.53	21.2
EtBr	4.79	20.5
C <sub>6</sub> H <sub>5</sub> Br, C <sub>6</sub> H <sub>5</sub> Cl	3.7	19.4
C <sub>6</sub> H <sub>6</sub>	2.23	22.2

<sup>a</sup> Dissociations are endothermic.

In the free-volume aspect, the effect of phase  
change has the direction expected and is greater than  
in the gas phase; there is much less dissociation in solution.  
Further, the effect of solvent change on the equi-  
librium constant is about one-third as large as the

Co., New York, N. Y., 1965, p 201.

A. Moelwyn-Hughes, "Kinetics of Reactions in Solution,"  
Oxford, 1947, p 184, from data of Cundall.

effect of phase change. Further, the heats of dissocia-  
tion vary erratically among the solvents and the spread  
is almost as great as between gas phase and carbon  
tetrachloride solution. The lack of correlation between  
K's and  $\Delta H$ 's shows that changes in entropies of solu-  
tion largely compensate for changes in enthalpy terms.

Table II shows that the same considerations apply  
in reaction rates as in the equilibria above. Rate con-  
stants for the dimerization of cyclopentadiene in var-  
ious media at 50° are listed in order of decreasing rate  
constants.<sup>2b</sup> Although the rate constants differ by  
a factor of only 3 (0.5 log unit), the erratic but compen-  
sating variations in frequency factors (40-fold) and in  
activation energies (2.7 kcal/mole) again suggest im-  
portant interactions of reactants and solvents.

Table II. Solvent Effects in the Dimerization of  
Cyclopentadiene<sup>2b</sup> at 50°

Solvent	-log k	log A	E, kcal/mole
Gas phase	5.2	6.1	16.7
CS <sub>2</sub>	5.2	6.2	16.9
Cyclopentadiene	5.2	5.8	16.2
AcOH	5.0	5.0	14.7
C <sub>6</sub> H <sub>6</sub>	5.0	6.1	16.4
CCl <sub>4</sub>	4.9	6.7	17.1
EtOH	4.7	6.4	16.4
C <sub>6</sub> H <sub>5</sub> NO <sub>2</sub>	4.7	5.5	15.1
Paraffin	4.7	7.1	17.4

The examples above show that the effects of solvent  
molecules on reacting solutes, whether they be com-  
plexing, solvation, or restriction of motion, and even  
with nonradical, nonpolar, nonhydrogen-bonding mate-  
rials, are usually about as large as, and sometimes much  
larger than, effects due to free volume or frequency of  
collision.

**Free Radical Reactions.** Table III classifies reactions  
of free radicals. Free radicals are commonly produced  
in pairs by decompositions of peroxides or azo com-  
pounds (reaction -1). They interact and destroy  
each other in pairs by reactions 1 (combination) or  
2 (disproportionation). Both reactions 1 and 2 cannot  
be avoided, and if these were the only reactions of free  
radicals, they would be of little interest. The interest  
arises from the other reactions which compete with  
reactions 1 and 2 and with each other. Reaction 3,  
usually the abstraction of a hydrogen or halogen atom  
(chain transfer in polymerization), is the most important  
and most studied reaction of free radicals. Reaction  
4, the addition of an atom or radical to a double or  
triple bond (or to oxygen), is an essential step in the  
free radical additions of many reagents to unsaturated  
compounds, usually in combination with reaction 3.  
Scission, reaction -4, is the reverse of 4, and is illus-  
trated by the loss of ethylene units from an alkyl radical  
and by the scission of *t*-butoxy to acetone and methyl.  
Reaction 5, rearrangement, corresponds to internal  
(unimolecular) abstraction or to other shifts of atoms  
or groups within radicals.

Of the eight listed reactions of free radicals in Table  
III, dissociation (-1), diffusion from cage (D), scission  
(-4), and rearrangement (5) are first-order reactions;  
the rest are bimolecular; occasionally 4 is termolecular.  
Reaction conditions are usually chosen to limit the

necessary for a cage effect; it can be demonstrated at high pressures of gases. In the photolysis of ethane in propane at 98° at pressures up to 50 atm the densities of the mixtures increased from 0.260 g/cc, the ethane:methane ratio increased from 0.063 to 0.10. This increase in ethane density that more propane does not supply more hydrogen atoms to methyl radicals as much as it favors cage combination. All of the ethane was formed in the cage.

**Combination and Disproportionation of Radicals (Reactions 1 and 2).** Here both competing reactions are second order and involve the same reactants. The effect of phase change are small.

Stefani, and Szwarc<sup>11</sup> measured the combination and disproportionation of ethyl radicals formed in the photolysis of ethane. The ratio of these rate constants was measured by a ratio of ethylene plus ethane to butane. In the gas phase, the ratio increased from 0.12 at +40° to 0.16 at -65°, independent of pressure (hence combination of two ethyl radicals does not require a body below 40°). In isooctane, the same ratio increased from 0.15 at 85° to 0.34 at -191°. Thus the competition between combination and disproportionation depends more on temperature than on reaction medium. These authors think that both reactions involve similar transition states, disproportionation is slightly favored by low temperatures and solvent cages.

**Reactions of Alkylperoxy Radicals.** The group at the Development Co.<sup>12</sup> was the first to suggest that combination of alkylperoxy radicals produces alkoxy radicals. It now appears that these reactions take place through decomposition of an unstable intermediate peroxide.<sup>13</sup> Decomposition of this intermediate produced alkoxy radicals in solution (apparently without the viscosity of the solvent<sup>14</sup>) but not in the gas phase.

Further, secondary and tertiary alkylperoxy and alkoxy radicals behave very differently. Since these reactions are still under investigation, discussion is deferred. However, these efficiencies of chain termination are important in determining kinetic chain lengths in the reactions of alkanes (see below) and in induced decompositions of hydroperoxides; phase changes are important because of cage effects.

**Molecular Abstractions of Hydrogen or Halogen (Reaction 3).** Hass, McBee, and Weber<sup>15</sup> made a classic study of the relative reactivities of primary, secondary, and tertiary carbon-hydrogen bonds toward chlorine in the chlorination of isopentane. Some of their experiments, carried out in both liquid and gas phases over a wide range of temperatures, are summarized in Table IV. In either phase the relative reactivities of primary, secondary, and tertiary hydrogen atoms approach unity with increasing temperature but the reactivity is lower in the liquid phase. Selectivity in the liquid phase at 100° corresponds to the low selectivity in the gas phase at 600°. The best explanation we know for this phase difference is the following. A chlorine atom in solution is so reactive and its lifetime is so short that its reactions depend on the details of a series of cage encounters ("cage effect") as well as on the relative reactivities of the surrounding

carbon-hydrogen bonds involved. It should follow that this liquid-phase-gas-phase difference will disappear as the attacking radicals become less reactive and their lifetimes become long compared with the times required for diffusion.

Table IV. Relative Rates of Reaction of C-H Bonds with Chlorine Atoms<sup>15</sup>

	Temp, °C	Tertiary	Secondary	Primary
Liquid phase	-60	13	8.5	1.00
	100	3	2	1.00
Gas phase	300	4.43	3.25	1.00
	600	3.5	2.2	1.00

This work has recently been corroborated and extended by Tedder and co-workers.<sup>16</sup> In the gas-phase chlorination of *n*-hexane<sup>16a</sup> in excess nitrogen at 40–212°, the relative reactivity of the total secondary and primary hydrogen atoms is  $k_s/k_p = (2.2 \pm 0.6) \exp[(214 \pm 127)/RT]$ . In a solution containing carbon tetrachloride, the corresponding relation for -70 to +39° is  $k_s/k_p = (0.8 \pm 0.2) \exp[(597 \pm 20)/RT]$ .

To the extent that these frequency factors and activation energies are reliable, the greater selectivity of the gas-phase chlorination at 39–40° ( $k_s/k_p = 3.11$  vs. 2.14) is due mostly to the ratios of the *A* factors (2.74 times as great in the gas) but largely offset by the activation energy term (0.54 times as great at 40° in the gas). These authors conclude that the effect of phase change on the ratios of the *A* factors is probably associated with the cage effect, but that the differences in the activation energies are probably associated with solvation of chlorine atoms in solution, even in the least polar solvents. (For a simple cage effect, selectivities should become more similar at increasing temperatures; instead, they diverge.)

They also compared reactivities in chlorination of various C-H bonds in normal acid chlorides and fluorides of 5–7 carbon atoms.<sup>16b</sup> They find that, in the gas phase, the acid halide group has no effect on reactivity of C-H bonds beyond the  $\beta$ -carbon atom, but in the liquid phase the effect of that group is readily detected at separations even of three additional carbon atoms. The effect of phase change is attributed to solvation in the transition state of the hydrogen chloride being formed.

When these results are compared with those of Russell and Walling<sup>17</sup> on complexing solvents in chlorination, their "noncomplexing solvents" (alkanes and carbon tetrachloride) must instead be weakly complexing solvents in comparison with benzene derivatives and carbon disulfide.<sup>16a</sup> Apparently, enough solvation to affect  $k_s/k_p$  by a factor of about 2 cannot be avoided in solution chlorinations.

No effect of phase change has appeared in competing abstraction reactions of methyl radicals, perhaps because they are less polar and less susceptible to solvation than reactions of chlorine atoms. Trotman-

(17) E. S. Huyser, "Advances in Free Radical Chemistry," Vol. 1, G. H. Williams, Ed., Academic Press Inc., New York, N. Y., 1965, p 77.

Dickenson<sup>18</sup> has measured the absolute rate constants for abstraction reactions of methyl radicals with various hydrocarbons in the gas phase at 100° by comparing these rates with those for combinations of methyl radicals. Edwards and Mayo<sup>19</sup> have measured the relative rates of abstraction reactions of methyl radicals, generated by decomposition of acetyl peroxide, with carbon tetrachloride and with hydrocarbons, all in solution at the same temperature. Table V shows that the relative reactivities of several kinds of carbon-hydrogen bonds in the two phases as measured by the two methods are nearly identical. The agreement also shows that phase change does not affect the competition between the bimolecular combination and abstractions.

Table V. Relative Rates of Reaction of C-H Bonds with Methyl Radicals at 100°

Compd	$k_{RH}$ , gas <sup>18</sup> at 100° × 10 <sup>6</sup>	$\frac{k_{RH}}{k_{CCl_4}}$ , soln <sup>19</sup> at 100°	$\frac{k_{RH}(\text{gas})}{k_{RH}/k_{CCl_4}(\text{soln})}$
Benzene <sup>a</sup>	0.091	0.04	2.3
Acetone	1.0	0.40	2.5
Toluene	1.9	0.75	2.5
1-Octene	7.7	3.2	2.4
Cyclohexane	3.4	4.5 <sup>b</sup>	0.8 <sup>b</sup>

<sup>a</sup> It now appears that methyl radicals do not abstract hydrogen directly from benzene but by a more complex process. <sup>b</sup> The discrepancy with cyclohexane is accounted for by the suggestion of DeTar and Wells<sup>20</sup> that the chain chlorination of cyclohexane by carbon tetrachloride depleted the concentration of carbon tetrachloride in the solution experiment.

**Additions of Free Radicals to Multiple Bonds (Reactions 4 and -4).** Additions of free radicals to oxygen or unsaturated compounds (4) are usually both exothermic and reversible; the reverse reaction is scission or cracking (-4). As in combinations of two radicals (1), when the radicals and molecules are small, a third body is needed to prevent immediate dissociation, as in reaction of methyl radicals with oxygen, a third-order reaction.

The importance of reversibility, even in the liquid phase below 100°, is demonstrated by the isomerization of *cis* to *trans* isomers by bromine atoms<sup>21</sup> and thiyl radicals,<sup>22</sup> and by ceiling temperatures in vinyl polymerization.<sup>23</sup> Mass action and enthalpy effects favor additions at higher concentrations and at lower temperatures; entropy effects favor scission in the gas phase at high temperatures. Benson<sup>24</sup> has recently calculated the effects of oxygen pressure and temperature on the fractional conversion of various alkyl radicals to the corresponding alkylperoxy radicals. His paper also shows the effects of changes in resonance stabilization of the initial and final radical on the balance between addition and scission.

Sivertz and co-workers have measured rates of additions of mercaptans to alkenes in the gas phase<sup>25</sup> and in benzene solution.<sup>26</sup> They report that over-all rates in the gas phase have a negative temperature coefficient which they attribute to the reversible addition of RS· radicals ("complex formation")

In benzene solutions, the over-all activation energies are positive but small; reversibility at normal concentrations is less important. Data are inadequate to tell much more about the effect of phase change. The gas-phase addition of hydrogen bromide to propylene<sup>27</sup> also has a negative temperature coefficient.

**Competition between Abstraction and Addition (Reactions 3 and 4).** Abstraction and addition reactions of free radicals often compete. Since only the addition reaction is immediately reversible, both concentration and temperature may affect comparison of gas-phase and liquid-phase reactions. From a 10% solution of chlorine and toluene at 0° in the dark, Kharasch and Berkman<sup>27</sup> found that 55% of the chlorine reacted by substitution in the side chain and 45% by addition to the benzene ring. On the other hand, the gas-phase chlorination of toluene would give only benzyl chloride. In solution, the addition of a chlorine atom to the benzene ring is readily followed by reaction with another chlorine molecule and completion of addition. However, at the lower concentrations and higher temperatures used in gas-phase reactions, the concentration of the free radical formed by addition of the chlorine atom is inadequate to support much addition. The irreversible displacement of a side-chain hydrogen atom is therefore the dominant reaction, and the observed product is benzyl chloride.

The chlorination of an alkene may occur by addition to the double bond to give a dichloride or by hydrogen abstraction to give an allylic chloride. In the gas-phase free radical reaction,<sup>28</sup> addition predominates at low temperatures and is replaced by allylic substitution at high temperatures. This shift seems to be due mostly to the reversibility of the addition of chlorine atoms to alkenes at high temperatures. In the liquid phase, the results are complicated by the intrusion of an ionic reaction. Thus, Burgin and co-workers<sup>29</sup> report that pure isobutylene and chlorine do not react in the gas phase in the dark below 150°. However, as soon as a liquid film appears at lower temperatures, methallyl chloride is formed very rapidly. This reaction is not affected by the presence of oxygen, which inhibits free radical chlorinations. Poutsma<sup>30</sup> has recently and ably extended this work. In the liquid phase most alkenes chlorinate by two mechanisms, one free radical and oxygen inhibited, the other ionic and not affected

oxygen. The ionic reaction gives mostly allyl substitution.

free radical chlorination gives both addition and substitution products, depending on the alkene. Here the change greatly affects the course of a chlorination because a competing polar reaction, requiring solution of ions, is possible only in the liquid phase.

The examples below describe abstraction and addition reactions of phenyl radicals with toluene and show that the change has little effect on other abstraction-addition competitions when the addition is not reversible.

Jacobs and Szwarc<sup>11</sup> discussed the effect of phase change on reactions of phenyl radicals with toluene. In solution, the reaction of phenyl radicals with toluene had been reported to produce only bibiphenyls, not bibenzyl. However, in the gas phase above 100°C, phenyl radicals react with toluene to give benzene and benzyl radicals; the principal product is bibenzyl. Only with the higher concentrations and lower temperatures usually associated with solutions is the concentration of the addition product of the phenyl radical to the benzene ring high enough for a hydrogen atom to be abstracted and for the reaction to be completed.

More recent work in solution has given better measures of the addition/abstraction ratio for reaction of phenyl radicals with toluene. For 80°C, Hey<sup>12</sup> gives 6.7. For 60°C, the data of Pryor<sup>13</sup> give 1.14. The apparent effect of temperature here is the opposite of that expected, but the results were obtained by different techniques. If scission of the phenyl radical-toluene adduct is fast, the addition/abstraction ratio is proportional to the concentration of phenyl radicals. Quantitative extensions of such work to other phases would be of interest. The addition/abstraction ratio is already known<sup>12,13</sup> to depend on substitution in the phenyl radical.

However, where the addition reaction is irreversible, the effect of phase change on the addition-abstraction competition is small. Jacobs and co-workers have measured the relative rates of reaction of fluoromethyl radicals with 2,3-dimethylbutane (by hydrogen abstraction,  $k_2$ ) and with a series of vinyl compounds (by addition, both the gas phase<sup>14</sup> and the liquid phase.<sup>15</sup> Differences in activation energies and frequency factors were measured in the gas phase from 65 to 180°C and in the liquid phase from 0 to 95°C. The relative reactivities of the alkenes, measured by  $k_2/k_1$  at 65°C, increased 200-fold when the least reactive, vinyl fluoride, is compared with the most reactive, 2,3-dimethyl-1,3-butadiene. This increase is due to a decrease in  $E_1 - E_2$ ; the  $A_1/A_2$  factors remain essentially constant. In the liquid phase<sup>15</sup> the values of  $E_1 - E_2$  are substantially the same as in the gas phase. The  $k_2/k_1$  and the  $A_1/A_2$  tended to be 20–30% larger on the average than the corresponding gas-phase values. In an earlier paper,<sup>16</sup> this phase difference was attributed to some lag in stabilization of the adduct in the gas phase. In this case, where addition is irreversible, phase change and the low free volume of the liquid affect the addition and abstraction reactions to about the same extent.

Jacobs and Mayo<sup>17</sup> studied the di-*t*-butyl peroxide initiated chlorination of ethylene and carbon tetrachloride at 140°C, in the liquid phase in three solvents, and in the gas phase at total pressures of 1–28 atm. The objective was to determine the effects of phase change and phase change on the variation with  $n$  of the

transfer constants of the radicals  $\text{Cl}_2\text{C}(\text{C}_2\text{H}_5)_n$ . The transfer constants,  $C_n$ , are defined as (rate constant for chlorine abstraction from  $\text{CCl}_4$  by  $\text{Cl}_2\text{C}(\text{C}_2\text{H}_5)_n$ )/(rate constant for addition of the same radical to ethylene); they measure directly the competition between reactions 3 and 4 of  $\omega$ -trichloroalkyl radicals. These transfer constants were known to change about 40-fold as  $n$  increased from 1 to 4 in the liquid phase at 70°C. Since this effect seems to be due to increasing separation of the trichloromethyl group from the free valence in the growing polyethylene radical, effects of both solvent change and phase change were expected. At 140°C, the effect of changing the solvent from *n*-octane to methanol hardly exceeded 30%. When the results in octane and at 1.2 atm in the gas phase are compared, the values of  $C_1$  are nearly identical and the indicated value of  $C_1$  in the gas phase is about twice the octane value. While the results for  $C_2$  and  $C_3$  are subject to more experimental error, phase change only exaggerates slightly the very large drift in  $C_n$  with increasing  $n$ .

**Competition between Chain Propagation (3 and 4) and Termination Reactions (1 and 2).** If propagation is fast enough, chain reactions can proceed nearly as well in normal low gas-phase concentrations as in the liquid phase. One example is the free radical chlorinations above. Another is the free radical addition of hydrogen bromide to double bonds.<sup>18,19</sup> On the other hand, while the photochemical addition of hydrogen sulfide to 1-butene would proceed readily in the liquid phase at 0 or –78°C, reaction under ultraviolet illumination in the gas phase at room temperature at a total pressure of 300 mm was very slow.<sup>20</sup> At this low concentration of reactants, one of the propagation steps was unable to compete with chain termination. These relations are complicated by the reversibility of the addition reaction and by the negative temperature coefficient of the over-all addition reactions in the gas phase.<sup>21</sup>

A similar situation arises in autoxidations. Although many initiated autoxidations proceed readily at or below 100°C in the liquid phase, gas-phase reactions of similar chain lengths require temperatures of 200°C or more at pressures of about 1 atm. This difference is largely an effect of reactant concentration on the competition between chain propagation and termination reactions. Although the initiated oxidation of isobutane gives chain lengths of only about one at a total pressure below 1 atm at 150°C, much longer chains can be obtained at superatmospheric pressures (see below).

**Competition between Abstraction (3) or Addition (4) and Rearrangement Reactions (5).** My discussion of the change in transfer constant with chain length in the telomerization of ethylene and carbon tetrachloride oversimplified the situation. In the liquid-phase reaction, kinetic chains are very long and only normal telomers are obtained. In the gas phase at 1 atm where the total concentration of reactants is only about 0.03 *M*, only 20–30% of the products obtained are normal telomers; the remaining 70–80% are isomers of normal telomers,<sup>22</sup> arising by rearrangement reactions such as

The rearrangements of the indicated radicals compete with both addition to ethylene (4) and abstraction from

carbon tetrachloride (3). The indicated products continue to react with ethylene and/or carbon tetrachloride to give telomer isomers. These rearrangements are due more to a concentration effect than to a phase change. As the concentrations of ethylene and carbon tetrachloride decrease, unimolecular rearrangements such as those above replace the normal bimolecular addition and displacement reactions. These rearrangements become less important at higher pressures in the gas phase. Such rearrangements become of increasing importance in solution in unreactive solvents.<sup>41</sup>

**Competition between Abstraction and Scission (Reactions 3 and -4).** Walling and co-workers have examined in detail the competition between the reactions

in chain decompositions of *t*-butyl hypochlorite where the fast complementary step is

Of special interest here are their measurements<sup>42</sup> of  $k_a/k_d$  at 5:1 ratios of cyclohexane and *t*-BuOCl in the gas phase, in several solvents, and at several temperatures. Some of their results are summarized in Table VI. Each  $k_a/k_d$  ratio represents the slope of a (linear) plot of *t*-BuOH/AcMe found against the concentration of cyclohexane in the gas phase or in the chosen solvent. Solvents are arranged in order of decreasing values  $k_a/k_d$ .

Table VI. Solvent Effects<sup>42</sup> on Reactions of *t*-Butoxy Radicals at 40°

Solvent	$k_a/k_d$	$E_d - E_a$	log $A_d/A_a$

<i>trans</i> - $\text{C}_2\text{H}_2\text{Cl}_2$	14.2	7.69	-4.16
<i>cis</i> - $\text{C}_2\text{H}_2\text{Cl}_2$	9.1	7.04	-3.92
MeCN	8.1	9.54	-5.73
AcOH	2.9	5.95	-3.66

In the gas phase, bimolecular hydrogen abstraction is favored over unimolecular decomposition by a factor of at least 10 in comparison with the liquid phase. Considerations of free volume or collision frequency predict a shift in the *opposite* direction. Thus, even in the most inert fluorocarbon solvent, solvation or cage effects far outweigh any effect of phase change expected from a noninteracting solvent. Among different solvents at 40°,  $k_a/k_d$  varies by a factor of up to 18. The differences in activation energies are erratic but mostly compensated by changes in ratios of *A* factors. Al-

though neither changes in  $E_d - E_a$  nor in  $\log (A_d/A_a)$  parallel those in  $k_a/k_d$ , changes in these factors mostly compensate each other, as in the equilibrium and non-radical reactions in the introductory section.

The effect of phase change on  $k_a/k_d$  is the largest one I know about in free radical reactions. Apparently solvation or complexing favors the unimolecular cleavage over the bimolecular hydrogen abstraction, but we cannot tell whether complexing promotes or hinders both competing reactions.

**Competition between Abstraction (3), Cleavage (-4), and Termination Reactions (1 and 2).** My last example deals with the oxidation of isobutane<sup>43</sup> in gas and liquid phases at 100–150°. This example shows how the competition of several reactions, each affected in a simple way by concentration changes with phase change, can affect both products and apparent rate constants. Table VII gives the liquid-phase products and the chain

Table VII. Products of Oxidation of Isobutane at 100–150°

steps through which they arise. In the gas phase at subatmospheric pressure at 155°, the principal products are acetone and methanol. Here, the concentration of isobutane is too low to support abstraction (6 in Table VII) in competition with reaction 8. The concentration of isobutane is also too low to support the bimolecular abstraction (9) in competition with the unimolecular cleavage (10). The resulting methyl radicals react with oxygen by an analog of reaction 7 and most of the resulting methylperoxy radicals are converted to methoxy radicals by an analog of reaction 9. As the pressure of isobutane is increased, displacement reactions 6 and 9 begin to replace chain termination and cleavage reactions 10. However, the methylperoxy and methoxy radicals are so much more reactive in chain termination than the corresponding *t*-butylperoxy or *t*-butoxy radicals, either with themselves or with the *t*-butyl derivatives, that a small proportion of surviving methyl radicals and their oxygenated derivatives retards the over-all rate of oxidation. A corresponding effect appeared when we diluted the liquid-phase oxidation with an inert solvent. Cleavage of *t*-butoxy radicals set in and decreased the effective value of  $k_p/k_t^{1/2}$  for the liquid phase. Thus, both the gas-phase and the liquid-phase values of  $k_p/k_t^{1/2}$  were complicated by methyl radicals from cleavage, and there were too many variables to isolate the effect of phase

e. We conclude that the effect of phase change is in comparison with other complications.

## Summary

rates and products of reactions of free radicals from competition among several alternative ones. The commonly large differences in concentration between liquid-phase and gas-phase reactions obscure obvious differences in gross rates of reaction.

The most important competing reactions are of first (and second) order, yields and products are fixed as well. Two other aspects of concentration can be experimentally important: the cage effect reaction, and the slowing of unimolecular reactions at pressures. The former can be observed, and the latter eliminated, at higher pressures in the gas phase. These effects are expected and largely predictable.

The most important contribution of this paper is to emphasize the importance of solvation in reactions of radicals in solution; perhaps there are no really free radicals in solution in the gas-phase sense.<sup>44</sup> Chemists have been slow to recognize this situation because nearly all our information comes from ratios of rate constants for competing reactions where solvation has little effect on both. However, in the cleavage and addition reactions of alkoxy radicals<sup>45</sup> there is a clear and clear effect of solvent and phase change.

In two reactions as similar as the reaction of a tertiary atom with a primary and a secondary hydroperoxide, an effect has now been detected.<sup>16a</sup> Other examples of solvation were the association of nitrogen dioxide and (in nonradical reactions) the dimerization of penta-1,3-diene and the chlorination of isobutylene. It appears that solvents interact to some extent with free radicals as well as ions and that gas-phase studies are

essential to establish the effects of zero solvation in liquid-phase reactions.

Since studies of competing reactions do not tell us whether these reactions are individually accelerated or retarded by solvation, it is important to measure the absolute rate constants for the same reaction at the same temperature in the gas phase and in solution. In further studies of competing reactions, a few more of the most and least polar reactions should be compared in the two phases to see if the distinction between chlorine atoms and alkyl radicals is as sharp as it now seems. The effects of remote substituents<sup>16b,23</sup> seem to be a sensitive tool. Because of the importance of reactions of aryl radicals with aromatic hydrocarbons, further work on the competition of addition and transfer reactions of alkylbenzenes<sup>27,31-35</sup> also seems desirable.

In choosing experimental conditions for practical synthesis through free radicals, the following factors deserve consideration. Liquid-phase reactions require small volumes and favor bimolecular reactions and cage products. Gas-phase reactions usually employ low concentrations which can moderate fast reactions, permit use of high temperatures without high pressures, favor unimolecular reactions, and eliminate cage reactions. High-pressure gas reactions resemble those in the liquid phase. However, the choice of phase depends mostly on consideration of the competing reactions in Table III and how the competition will be affected by phase or concentration changes.

Finally, wall effects are much more important in gas-phase reactions, where diffusion is faster, than in liquid-phase reactions. However, in reactions on walls or in heterogeneous catalysis we are not concerned with free radicals but with bound or complexed radicals which are beyond the scope of this paper.

**Acknowledgment.** The author appreciates careful readings of this paper and/or numerous useful suggestions by Drs. S. W. Benson, David M. Golden, William A. Pryor, and Cheves Walling.

## Rotation of Styrene and *t*-Butylethylene in Platinum(II) Complexes with 2,4,6-Trimethylpyridine

Allan R. Brause, Fred Kaplan, and Milton Orchin

Contribution from the Department of Chemistry, University of Cincinnati, Cincinnati, Ohio 45221. Received January 13, 1967

**Abstract:** Several 1,3-dichloro-2-olefin-4-(2,4,6-trimethylpyridine)platinum(II) complexes, 2, have been prepared and their nmr spectra determined. Although at room temperature there is a single signal for the 2,6-methyl groups, at about  $-50^\circ$  the signal splits. This behavior is interpreted to indicate rapid (on the nmr time scale) rotation of the olefinic species about its coordination axis and a "freezing out" at the lower temperature.

Zeise's anion, 1, ethylene is known to be oriented at right angles to the square plane in the crystal.<sup>1</sup> In connection with some other work<sup>2</sup> in this

A. Wunderlich and D. P. Mellor, *Acta Cryst.*, 7, 130 (1954).  
A. R. Brause and M. Orchin, submitted for publication.

laboratory, we prepared 1,3-dichloro-2-ethylene-4-(2,4,6-trimethylpyridine)platinum(II), 2, R = H. Although the compound is almost certainly *trans*, the exact spatial arrangement of the ligands with respect to each other is of interest.

The exceptional stability of *ortho*-substituted aryl nickel complexes, e.g., *trans*-[(PPhEt)<sub>2</sub>Ni(mesityl)<sub>2</sub>], has been ascribed<sup>3</sup> to the interference of the *ortho* substituents with the bulky tertiary phosphine ligands on each side of the nickel atom which prevents rotation of the aryl group about the Ni-C bond. Although there may be some question as to the validity of the interpretation, it is quite clear that substantial steric hindrance to free rotation exists. In **2**, rotation round the Pt-N coordination bond as an axis is possible, but molecular models show that 2,6-methyl substitution would favor a geometry in which the pyridine ligand lies perpendicular to the square plane as shown. Although the ethylene group also might be perpendicular to the square plane as in **2**, the possibility of ethylenic rotation in solutions of the complex needs to be considered. If we involve the d<sub>xy</sub> orbital in the dsp<sup>2</sup> hybrid bonding orbitals,<sup>4</sup> then the availability of the d<sub>xy</sub> orbital for d-π\* bonding should facilitate such rotation. Indeed, Cramer has shown<sup>5</sup> that the ethylene coordi-

nated to rhodium(I) in the compound π-C<sub>6</sub>H<sub>5</sub>Rh(C<sub>2</sub>H<sub>4</sub>)<sub>2</sub> rotates freely at room temperature.

In the complex **2** (R = H), the *o*-methyl groups are in magnetically equivalent environments with respect to ethylene. If, however, an unsymmetrical olefin were complexed in place of ethylene and the pyridine moiety were "fixed," the *o*-methyls would become nonequivalent and such nonequivalence should be discernible by nmr techniques. Accordingly, the complexes **2** (R = CH<sub>3</sub>, C(CH<sub>3</sub>)<sub>3</sub>, Ph) were prepared. A single nmr resonance for the *o*-methyls would be presumptive evidence for free rotation of the olefin; splitting of the singlet at low temperature would be consistent with slowing down such rotation.

## Experimental Section

1,3-Dichloro-2-ethylene-4-(2,4,6-trimethylpyridine)platinum(II), **2** (R = H), was prepared by addition of 2,4,6-trimethylpyridine to Zeise's salt<sup>6</sup> in 97% yield as a yellowish green powder, mp 155–157° dec (2-mmole scale). *Anal.* Calcd for PtCl<sub>2</sub>C<sub>10</sub>H<sub>11</sub>N: C, 28.91; H, 3.64; Pt, 46.99. Found:<sup>6</sup> C, 29.12; H, 3.85; residue (Pt), 46.60.

Compound **2**, (R = CH<sub>3</sub>) was synthesized *via* the propylene platinumous chloride dimer. Simple displacement of ethylene by propylene from the ethylenic complex gave incomplete conversion. The ethylene platinumous chloride dimer (500 mg, 0.85 mmole) was placed in a small vial and immersed in a Dry Ice-acetone bath. Propylene was bubbled in until about 5–7 ml had accumulated, and then the mixture was stirred magnetically at this temperature for 15 min. The Dry Ice bath was removed, and the mixture was stirred at room temperature until all the excess propylene had evaporated. Saturated potassium chloride solution was added, and the solution was stirred until no more solid material remained and a yellowish green solution resulted. Then 0.30 ml of 2,4,6-trimethylpyridine (1.95 mmole, 15% excess) was slowly added, giving a yellow-green cloud and then a precipitate on standing. This was filtered and air dried, yielding 657 mg (90%) of a yellow powder, mp 103–105° dec. *Anal.* Calcd for PtCl<sub>2</sub>C<sub>11</sub>H<sub>13</sub>N: C, 30.76; H, 3.99; Pt, 45.46. Found:<sup>6</sup> C, 30.05; H, 3.94; residue (Pt), 46.90.

Compound **2** [R = (CH<sub>3</sub>)<sub>2</sub>C] was made by the same dimeric route, except in this case no ice bath was necessary as the boiling point of *i*-butylethylene is 76°. From 1146 mg of impure dimer, which was first dissolved in acetone and filtered to remove impurities, there was obtained 1004 mg (55%) of a yellow-green powder, mp 129–133° dec. *Anal.* Calcd for PtCl<sub>2</sub>C<sub>14</sub>H<sub>22</sub>N: C, 35.65; H, 4.92; Pt, 41.40. Found:<sup>6</sup> C, 34.80; H, 4.83; residue (Pt), 36.60.

Compound **2** (R = Ph) was efficiently prepared by simple displacement. The ethylenic complex (958 mg, 2.30 mmole) was dissolved in 25 ml of chloroform and 0.25 ml (2.2 mmole) of styrene was added. The mixture was stirred magnetically for 30 min, then filtered, giving a clear yellow solution. The volume of solution was reduced with a nitrogen stream and pentane was added, giving a yellow-orange oil which on scratching and refrigeration overnight gave a highly crystalline orange-yellow material, mp 133–135° dec, yield 769 mg (68%). *Anal.* Calcd for PtCl<sub>2</sub>C<sub>16</sub>H<sub>15</sub>N: C, 39.09; H, 3.90; Pt, 39.72. Found:<sup>6</sup> C, 38.45, H, 4.08; residue (Pt), 40.70.

Attempts to prepare 1,3-dichloro-2(α,α-diphenylethylene)-4-(2,4,6-trimethylpyridine)platinum(II) by either simple displacement or *via* the dimer were unsuccessful. A previous attempt to prepare the α,α-diphenylethylene dimer<sup>7</sup> was also unsuccessful.

## Results and Discussions

The nmr spectral data are given in Table I. Our discussion shall concern itself only with the signals for the *o*-methyl groups. When the propylene complex **2** (R = CH<sub>3</sub>) was examined only a single triplet (Figure 1) was observed for the *o*-methyls and there was no significant change at –46°. Owing to instrumental limitations, the temperature could not be much further lowered. We then decided to increase the

(3) J. Chatt and B. L. Shaw, *J. Chem. Soc.*, 1718 (1960). These authors suggest that the perpendicular orientation of the aryl ring forces interaction between a π orbital of the aryl group and the d<sub>xy</sub> orbital in the plane of the molecule. Since both of the orbitals to be combined are occupied, this should lead to a raising of the highest occupied (dπ) orbital and hence a lowering of the energy difference between the highest occupied and lowest empty orbitals.

(4) We are using essentially the coordinate system employed by J. W. Moore, *Acta Chem. Scand.*, 20, 1155 (1966), in his complete treatment of the electronic absorption spectrum of Zeise's salt. The anion, **1**, and compound **2** (R = H) have C<sub>2v</sub> symmetry and hence the necessity of using the symmetry axis in the square plane as the z axis. In PtCl<sub>4</sub><sup>2-</sup>, the z axis is the fourfold symmetry axis perpendicular to the plane.

bulk of the R group and prepared the compound 2 where R = Ph. The single triplet observed in the nmr at room temperature was split into two overlapping triplets at -60°; the chemical shifts of the two triplets were δ 2.93 (*J*<sub>Pt-CH<sub>3</sub></sub> ~ 12 cps) and δ 2.80 (*J*<sub>Pt-CH<sub>3</sub></sub> ~ 12 cps), a chemical shift difference of 7.8 cps at 60 Mc. The same effect was observed with compound 2 (R = *t*-butyl) although it was not as pronounced, and a difference of only 2 cps in the chemical shift was observed

moieties free to rotate at room temperature and both frozen out at low temperatures. We do not consider either of these as likely as the "fixed" pyridine and the rotating ethylene. Rapid intermolecular exchange of free and complexed olefin would also account for the observation of a single absorption for the *o*-methyls. However, the spectrum of 2 (R = Ph) shows platinum-olefin coupling at room temperature and thus this explanation is excluded.

Figure 1. Nmr spectra of *o*- and *p*-methyls in the propylene complex.

Figure 2. Nmr spectra of *o*-methyls for R-substituted complexes.

(Figure 2). Since we assume that the pyridine is relatively fixed in these complexes, a single signal for the *o*-methyls in the styrene and *t*-butylethylene complexes implies a rotation of the vinyl compound around the coordination axis. Lowering the temperature "freezes" out the rotation and permits observation of the more stable conformer in the nmr spectra. Alternately, we could have considered that the olefin is fixed and the pyridine rotating at room temperature and frozen out at low temperature. Or, we may have considered both

Failure to observe splitting with the propylene complex 2 (R = CH<sub>3</sub>) may mean a smaller rotational barrier requiring temperatures lower than -60° or it may mean that the magnetic effect of the propylene on the *o*-methyl groups is too small to be observed across the square plane.

A decision as to whether the ethylenic moiety is frozen out parallel to or perpendicular to the square plane

could presumably be made by using  $\alpha,\alpha$ -diphenylethylene in place of ethylene in 2. If both phenyls were either above or below the square plane, two signals for the *o*-methyls should be observed. However, if the diphenylethylene were frozen out so that one phenyl was above and one phenyl below the plane, the *o*-methyls would again be magnetically equivalent and only one signal should result. Unfortunately, the compound of interest could not be prepared, but the investigation is being pursued.

**Acknowledgment.** The authors wish to thank Dr. P. Kaplan, Dr. W. W. Bannister, and Mr. Paul Schmidt for their valuable comments, and Mr. Frank Stary for some assistance with the Varian A-60. This research was partially supported by the Sohio Corp. through a fellowship to Mr. Brause. Further, we should like to thank Engelhard Industries for donating our platinum supplies. The nmr spectrometer used in this work was purchased with the aid of a grant from the National Science Foundation.

## Catalysis of $\alpha$ -Hydrogen Exchange. IV. Deuterium Exchange of Methoxyacetone<sup>1,1a</sup>

Jack Hine, K. Gerald Hampton,<sup>2</sup> and B. C. Menon

*Contribution from the Evans Laboratory of Chemistry, The Ohio State University, Columbus, Ohio 43210. Received January 14, 1967*

**Abstract:** The kinetics of loss of deuterium from methoxyacetone containing deuterium  $\alpha$  to the carbonyl group have been studied in aqueous solution. Catalytic constants have been determined for hydrogen ions, hydroxide ions, water, phenoxide ions, *p*-nitrophenoxide ions, trimethylamine, triethylamine, N-methylpyrrolidine, and N-methylmorpholine. In the presence of N-methylmorpholine buffers the reaction is slightly subject to catalysis by methylammonium chloride, presumably because of the intermediate formation of an enamine. Exchange at the methyl position is faster (by up to sixfold) than at the methylene position for all the catalysts studied except hydroxide ions, which brought about slightly more rapid exchange at the methylene position.

Many physiologically important reactions, such as aldol condensations, epimerizations, etc., involve deprotonation of an organic molecule (*e.g.*, a sugar) at a position that is  $\alpha$  to a carbonyl group and to a hydroxy group. As a first step in studying the mechanisms of such reactions we have investigated the deuterium exchange of methoxyacetone. The methoxy substituent should have an influence on the acidity of hydrogen atoms attached to the same carbon atom that is quite similar to that of a hydroxy substituent, but the greater difficulty of oxidizing and deprotonating the methoxy substituent should decrease the probability of complicating side reactions.

### Results

The proton magnetic resonance (pmr) spectrum of methoxyacetone consists of three singlets, at  $\tau$  5.97, 6.59, and 7.87, attributed to the methylene hydrogen atoms, the methoxy hydrogen atoms, and the carbon-bound methyl (referred to hereafter simply as methyl) hydrogen atoms, respectively, on the basis of their relative intensities and chemical shifts. When solutions of the compound in deuterium oxide are heated with sodium carbonate, the absorption due to the methylene and methyl hydrogen atoms decreases in intensity. We

have studied the catalytic action of hydrogen ions and various bases on the dedeuteration of the deuterated methoxyacetone prepared in this way. The reaction was followed by extracting the aqueous reaction solutions with chloroform and integrating the pmr spectra of the chloroform extracts. The methoxy group of the ketone provides an internal standard for comparison with the increasing intensities of the other two absorption peaks. First-order rate constants were determined using the equation

$$k_p t = 2.303 \log \frac{(M/R)_\infty - (M/R)_0}{(M/R)_\infty - (M/R)_t} \quad (1)$$

where  $R$  is the integrated intensity of the reference (methoxy) peak,  $M$  is the integrated intensity of the methyl or methylene peak, and the subscripts refer to the reaction time. For  $(M/R)_\infty$  the theoretical values, 1 for methyl and  $2/3$  for methylene, were used. For each run two rate constants may be calculated, one for loss of deuterium from the methylene group ( $k_p^{\text{CH}_2}$ ) and one for loss of deuterium from the methyl group ( $k_p^{\text{CH}_3}$ ).

It is assumed that the reaction is subject to catalysis by all the acids and bases present in the solution, so that in the presence of the B-BH<sup>+</sup> buffer the first-order rate constant  $k_p$  may be expressed

$$k_p = k_H[H^+] + k_{OH}[OH^-] + k_w[H_2O] + k_B[B] + k_{BH}[BH^+] \quad (2)$$

where the  $k$ 's are catalytic constants for the various possible catalysts. Superscripts will be used to show

whether a given catalytic constant refers to attack on the methyl or methylene side of the reactant.

The catalytic constant for hydrogen ions was determined by measurements using 0.5 *M* perchloric acid, with the result shown in Table I. Catalysis by other catalysts is negligible under these conditions. From the value of  $k_H$  obtained it follows that catalysis by hydrogen ions would never contribute as much as 10<sup>-5</sup>% to the over-all reaction rate in any case except the runs with pure water, which will be discussed separately.

The catalytic constants for hydroxide ions shown in Table I give average values of  $1.6 \times 10^{-2}$  and  $1.2 \times 10^{-2} M^{-1} \text{sec}^{-1}$  for  $k_h \text{CH}_3$  and  $k_h \text{CH}_2$ , respectively. The ratio of the catalytic constants for hydroxide ions to those for hydrogen ions ( $7 \times 10^4$  and  $4 \times 10^4$  for attack on the methylene and methyl hydrogen atoms, respectively) is larger than in the case of isobutyraldehyde,<sup>3</sup> where it is  $1.3 \times 10^3$ . Since only the acetate ions in acetate buffers were found to catalyze the dedeuteriation of isobutyraldehyde-2-*d* significantly, it was assumed that in the present case, where the sensitivity to base catalysis relative to the sensitivity to acid catalysis is even greater and where all the buffers used contained bases much stronger than the acetate ion and acids much weaker than acetic acid, all the catalytic action of the buffers used was due to the buffer bases; i.e., the  $k_{BH}$  term in eq 2 may be neglected.

The catalytic constant for water is too small to be determined conveniently at 35°. Therefore the runs in which no catalyst (other than the solvent water) was added were carried out at 100 and 133°. From the results, shown in Table I, Arrhenius activation energies of 23.3 and 21.8 kcal/mole were calculated for reaction at the methylene and methyl positions, respectively. These activation energies were used to calculate the rate constants at 35°, which are also listed in Table I. Because of a small amount of impurity in the deuterated methoxyacetone used, the reaction solutions used for

determining  $k_w$  had a pH of about 4.6. After 240 hr at 133° the pH had dropped to about 3.5. It is, therefore, possible that some of the deuterium exchange observed is due to catalysis by acid or some other catalyst other than water. Hence the catalytic constants determined for water should be regarded as maximum values. Although the  $k_w$ 's may thus be the least reliable of the catalytic constants that we have determined, the values obtained do show that the  $k_w$  terms will not contribute more than 0.2% to the rate of reaction in any of the other runs made except the one in which perchloric acid was used, where a contribution as large as 1% is possible. Hence for the runs made using buffers, the  $k_w$  terms may also be neglected and eq 2 may be written in the form

$$k_B[B] = k_p - k_h[\text{OH}^-] \quad (3)$$

In order to use eq 3 to determine values of  $k_B$ , the basicity constants of the buffer bases (or the acidity constants of the buffer acids and the ion-product constant of water) are needed under the conditions of the kinetic experiments, so that the concentrations of hydroxide ions present in the various runs may be calculated. The thermodynamic  $pK_a$  at 35° may be interpolated from the data of Everett and Wynne-Jones<sup>4</sup> for trimethylammonium ions (9.58). The value for triethylammonium ions (10.45) was reported by Fyfe;<sup>5</sup> the values for phenol (9.86) and *p*-nitrophenol (7.03) were calculated from the values at 25° and the enthalpies of ionization determined by Fernandez and Hepler;<sup>6</sup> the values for N-methylmorpholine (7.17) and *n*-methylpyrrolidinium ions (10.14) were calculated from the values at 25°<sup>7,8</sup> and Perrin's method of mak-

ing temperature corrections.<sup>9</sup> According to the simplest form of the Debye-Hückel equation the acidity constant of an acid of charge type plus one should not change with changing ionic strength. Because of the difficulty in determining all the appropriate salt effects we have assumed that the acidity constants of all the substituted ammonium ions in our reaction solutions are the same as they are at infinite dilution, in spite of the fact that we have found that the acidity constant of 2,6-lutidinium ions changes when salts are added, in one direction when the salt is sodium chloride or methylammonium chloride and in the opposite direction when it is 2,6-lutidinium chloride.<sup>1b</sup> We have assumed that the ion-product constant of water is  $4.06 \times 10^{-14}$  in all our runs at ionic strength 0.50 *M*, although this figure refers to measurements at 35° in which essentially all the 0.50 *M* ionic strength was due to sodium chloride.<sup>10</sup> We have also assumed that the ionization constants of all electrically neutral acids change with added salt in the same way that the ion-product constant of water does. With these assumptions it was possible to calculate the hydroxide ion concentrations needed for use in eq 3. In the two runs with triethylamine the calculated value of  $k_h \text{CH}_3[\text{OH}^-]$  was 32–41% of  $k_p \text{CH}_3$  and  $k_h \text{CH}_3[\text{OH}^-]$  was 11–15% of  $k_p \text{CH}_3$ . With the other weak bases the extent of hydroxide ion catalysis is less, falling below 0.1% for *N*-methylmorpholine and sodium *p*-nitrophenoxide. Therefore, uncertainties in the ionization constants from which the hydroxide ion concentrations were calculated may result in errors in  $k_B$ . There are some compensating effects, however. If the ionization constant of a base is increased, then  $[\text{OH}^-]$  is increased and  $k_p - k_i[\text{OH}^-]$  decreased, tending to decrease  $k_B$ . However, since the value of  $[\text{B}]$  to be used in eq 3 is not the titrimetric value listed in Table I but the actual value present at equilibrium in solution ( $[\text{B}]_{\text{titrimetric}} - [\text{OH}^-]$ ), an increase in  $[\text{OH}^-]$  will also tend to increase  $k_B$ . In a case like that of  $k_B \text{CH}_3$  for *N*-methylpyrrolidine, which is of almost the same size as  $k_h \text{CH}_3$ , the two effects nearly cancel and very little uncertainty in  $k_B$  results from uncertainty in the ionization constant of the base; that is, the reaction rate is very little affected by the amount of pyrrolidine that deprotonates water to give hydroxide ions since the reactivity of the hydroxide ions is about the same as that of the pyrrolidine.

The catalytic activity of methylammonium chloride was investigated for the reaction carried out in the presence of *N*-methylmorpholine buffers with the results shown in Table II. Inasmuch as the catalytic activity of water, hydrogen ions, and hydroxide ions are all negligible in the presence of *N*-methylmorpholine (*Nmm*) buffers, the first-order rate constant for the reaction would be expected to be equal to  $k_{\text{Nmm}}[\text{Nmm}]$  if there were no catalysis by the methylammonium ions. Hence the quantity  $k_p - k_{\text{Nmm}}[\text{Nmm}]$  is a measure of the extent of catalysis by methylammonium ions. The amount of catalysis observed in the runs with 0.100 *M* methylammonium chloride is too small to be clearly significant. With 0.300 *M* methylammonium chloride it seems clear that there is catalysis by methylammo-

nium ions (or by some species derived from methylammonium ions).

## Discussion

If  $k_1$  is the rate constant per deuterium for the removal of a deuterium from the methylene group of methoxyacetone and if there is no secondary deuterium kinetic isotope effect, we may write

Let  $[\text{D}]$  be the total concentration, in equivalents, of deuterium in the methylene group.

$$[\text{D}] = 2[\text{AcCD}_2\text{OMe}] + [\text{AcCHDOMe}]$$

Then the rate of loss of deuterium from the methylene group may be expressed

$$\begin{aligned} d[\text{D}]/dt &= [\text{B}](2k_1[\text{AcCD}_2\text{OMe}] + k_1[\text{AcCHDOMe}]) \\ d[\text{D}]/dt &= k_1[\text{B}][\text{D}] \end{aligned}$$

Thus, if only one base is catalytically important, the reaction is expected to follow the first-order eq 1 in which  $k_p$  is equal to  $k_1[\text{B}]$  ( $[\text{B}]$  does not change during a given run), where  $k_1$  is the rate constant *per* deuterium. Analogous derivations may be made for methyl exchange and for exchange due to the simultaneous action of several catalysts to show that the catalytic constants we have listed in Table I are statistically corrected rate constants.

Although we observed no consistent tendency for our rate constants to drift either up or down, secondary kinetic isotope effects, which we have neglected, could cause such a tendency. This fact added somewhat to the uncertainty in the rate constants calculated from our data.

Our results show that the methyl hydrogens are removed more rapidly than the methylene hydrogens by every catalyst except hydroxide ions. This is certainly not the result to be expected from the inductive effect of the methoxy substituent. Discussion of the rate effect in terms of the relative stabilities of the two possible carbanions is hampered by our ignorance of which of the two is really the more stable. If the mechanism of the acid-catalyzed deuterium exchange is the following

(9) D. D. Perrin, *Australian J. Chem.*, **17**, 484 (1964).

second step (and an analogous step for exchange at the methyl position) being rate controlling, compound with a methoxy group attached to a bond is being formed in the rate-controlling reaction. In view of the known ability of oxygen substituents to stabilize double bonds,<sup>11-15</sup> it can be assumed that the enol resulting from reaction at the methylene side would be more stable than the enol resulting from reaction at the methyl side. This is supported by the report that methoxyacetone contains 1.1% enol,<sup>16</sup> a much larger enol content than that of acetone.<sup>17,18</sup> Thus, it appears that the rapid acid-catalyzed deuterium exchange at the methylene position of methoxyacetone is an example of a resonance-stabilized reaction in which the less stable product is formed more rapidly. A number of rate-equilibrium reactions of this type have been observed and some can be rationalized in terms of the principle of least motion.<sup>19</sup> According to the principle of least motion, the formation of 1-methoxy-2-hydroxypropene should tend to cause this enol to be formed more rapidly than 3-methoxy-2-hydroxypropene, the reverse possibility. However, the magnitude of the change in bond length to be expected is so small (compare the changes in bond lengths in the cases previously considered<sup>19</sup>) that only a very small effect would be expected.

It has been suggested that the increased electronegativity of  $\text{sp}^2$  carbon may tend to slow reactions in which the carbon whose hybridization changes from  $\text{sp}^3$  to  $\text{sp}^2$  carries a highly electronegative substituent. This has been discussed in more detail in connection with the effect of  $\alpha$ -methoxy and  $\alpha$ -fluoro substituents on the ease of carbanion formation by esters.<sup>20</sup> An attempt to rationalize the present data it should be noted that the relative rates of exchange at the methine and methylene positions do not constitute a fair comparison of the methoxy substituent with a hydrogen substituent. The comparison is of a methoxy and a hydrogen substituent with a hydrogen and a methoxyacetyl substituent.

Figure 1 is a Brønsted plot for the buffer bases. The points for water and hydroxide ions were included to permit the use of a scale that would make it

Figure 1. Brønsted plot for deuteriation of methoxyacetone at the methyl, O, and methylene, ●, positions.

easier to see the relationship between the points for the other bases. The points plotted certainly do not describe a good straight line for either the methyl or methylene exchange reaction, but they fall nearer straight lines than the points for the same bases in the exchange of isobutyraldehyde.<sup>3</sup> This is probably at least partly due to a decrease in steric effects. Triethylamine, which is more than seven times as basic as trimethylamine, was only  $1/30$  as reactive as trimethylamine toward isobutyraldehyde;<sup>3</sup> it is more than one-half as reactive as trimethylamine toward either the methyl or the methylene hydrogen atoms of methoxyacetone. The points for the two phenoxides used may be considered to describe Brønsted lines with slopes of about 0.62. This is somewhat larger than the slope (0.53) obtained from data on eight phenoxide ions in the case of isobutyraldehyde. The points for trimethylamine do not lie as far above these lines as the point for trimethylamine lay above the Brønsted line for phenoxide ions in the exchange of isobutyraldehyde. Instead it is roughly collinear with the points for N-methylpyrrolidine and N-methylmorpholine. This suggests that attack of the two cyclic amines on isobutyraldehyde was slowed by steric hindrance but that their attack on methoxyacetone is not. The fact that tertiary amines often remove hydrogen more rapidly than do primary or secondary amines of equal basicity<sup>21,22</sup> cannot be explained in terms of steric hindrance, however.

A Brønsted plot on a scale that permits inclusion of the points for water and hydroxide ions shows that water is somewhat less reactive than would be expected from the Brønsted line for phenoxide ions or a Brønsted line that could be drawn through the points for trimethylamine, N-methylpyrrolidine, and N-methylmorpholine. This type of behavior has been observed in several (but not all) other general-base-catalyzed reactions<sup>2,23,24</sup>

Figure 2. Kinetic plot for the dedeuteriation of deuterated methoxyacetone in the presence of sodium hydroxide at the methyl, O, and methylene, ●, positions.

and is in agreement with an expected tendency for the slope of the Brønsted line ( $\beta$ ) to decrease with increasing strength of the bases studied.<sup>25</sup>

The hydroxide ion is much less reactive than would be expected from the Brønsted line for phenoxide ions or the Brønsted line for unhindered tertiary amines. Toward the methyl group of methoxyacetone it is even somewhat less reactive than N-methylpyrrolidine, although it is about 100,000 times as strong a base as the amine. Bell has pointed out that this anomalously low reactivity of hydroxide ions occurs rather commonly;<sup>26</sup> it was observed in the deuterium exchange of isobutyraldehyde.<sup>3</sup>

The effect of methylammonium chloride on the reaction rate shows that the deuterium exchange of methoxyacetone is catalyzed by methylammonium ions but that it is much less susceptible to such catalysis than is the deuterium exchange of isobutyraldehyde. From the data in Table II and related data in Table I it may be seen that the addition of 0.300 *M* methylammonium chloride to a 0.200 *M* N-methylmorpholine–0.200 *M* N-methylmorpholinium buffer increases the reaction rate by about 50–70%. In the case of isobutyraldehyde, the rate of exchange in the presence of a 0.21 *M* N-methylmorpholine–0.21 *M* N-methylmorpholinium buffer is more than doubled by addition of 0.176 *M* methylammonium chloride.<sup>26</sup> The catalysis by methylammonium ions is probably due to the reversible formation of a deuterated imine and then a deuterated iminium ion, which is rate controllingly transformed to an enamine.<sup>1b,27</sup> The greater susceptibility of iso-

butyraldehyde to such catalysis may be due in part, at least, to a larger equilibrium constant for imine formation. In view of the larger equilibrium constants for semicarbazone formation that have been observed for aldehydes (compared to the constants for related ketones)<sup>28,29</sup> the aldehyde would be expected to have a larger equilibrium constant for imine formation.

### Experimental Section

**Deuterated Methoxyacetone.** Methoxyacetone was prepared by oxidizing 1-methoxy-2-propanol with aqueous sodium dichromate and sulfuric acid.<sup>30</sup> The material thus obtained contained up to 10% unoxidized starting alcohol. Except in one run in which only 2% alcohol was present, the methoxyacetone was purified by preparative gas–liquid partition chromatography using a stationary phase of silicone fluid XF-1150 to give material containing 1% alcohol or less. The pmr spectrum of the product in deuteriochloroform showed singlets at  $\tau$  5.97, 6.59, and 7.87 with relative areas of 2.3:3.

A solution of 33 g (0.375 mole) of methoxyacetone and 0.5 g of anhydrous sodium carbonate in 37.5 g (1.87 moles) of deuterium oxide was heated at reflux for 7 hr, then cooled and extracted with several 25-ml portions of ether. The ether solution was dried over anhydrous sodium sulfate and filtered, and the ether evaporated to give a residue that was passed through the deuteration procedure again. The residue from the second deuteration was distilled through a spinning-band column to give 12 g of deuterated methoxyacetone, bp 109–112°. The pmr spectrum of the product showed peaks at  $\tau$  5.97, 6.59, and 7.87 with relative areas of 0.24:3.0:0.36. The  $\tau$  5.97 and 7.87 peaks were significantly broader than the corresponding peaks in undeuterated methoxyacetone.

**Kinetic Runs.** In a typical run 2.0855 g of deuterated methoxyacetone and 16.5 ml of 3.0 *M* aqueous sodium chloride solution were diluted to volume in a 50-ml volumetric flask at 35.0°. From this flask 3-ml samples were transferred by pipet to each of a number of 10-ml volumetric flasks that already contained 3 ml of 0.01 *M* aqueous sodium hydroxide. At a recorded time the reaction in each flask was stopped by the addition of a small excess of acetic acid, and then the solution was extracted with chloroform. The pmr spectrum of the chloroform extract was integrated several times. Rate constants were determined by plotting the right-hand side of eq 1 against time. In this run, as in the others in which sodium hydroxide was used as the catalyst, the plot (Figure 2) showed curvature (corresponding to a decrease in the first-order rate constant) after about 20% reaction, and therefore only the data for the first 20% of the reaction were used. No such curvature was noticed in the other runs, which were usually followed to 50–75% completion. In the cases of some catalysts, where there was a rather large difference between the rates of exchange at the methyl and methylene positions, the rate constant for exchange at the methyl position was determined from a series of points taken before very much exchange had taken place at the methylene position, and the rate constant for exchange at the methylene position was determined from a series of points taken after exchange at the methyl position was almost complete.

The methoxyacetone used contained a small amount of an unidentified acidic impurity that gave the initial reaction solution a pH of about 4 due to an acid content around 0.001 *M*. In the most vigorous conditions used for any of the reactions (133°) the pH dropped to 3.5 and the acid content rose to 0.004 *M* after a time four times as long as that used for the last kinetic point taken. Because of the presence of these small amounts of acidic impurities, the catalytic constants we have reported for basic catalysts will tend to be too low. This will be significant only in cases where the concentrations of basic catalysts are relatively small. The errors resulting from these impurities must not be very large, because if they were we would not get about the same catalytic constant using significantly different concentrations of catalysts.

**Acknowledgments.** We wish to acknowledge our indebtedness to the National Science Foundation for a grant that permitted the purchase of the nmr spectrometer used in this investigation, and to Dr. John P. Idoux for experimental assistance.

# Equilibrium in Formation and Conformational Isomerization of Imines Derived from Isobutyraldehyde and Saturated Aliphatic Primary Amines<sup>1</sup>

Jack Hine<sup>2</sup> and Chuen Yuan Yeh

Contribution from the Evans Laboratory of Chemistry, The Ohio State University, Columbus, Ohio 43210, and the School of Chemistry, Georgia Institute of Technology, Atlanta, Georgia. Received January 28, 1967

**Abstract:** The following dimensionless equilibrium constants were determined for the formation of imines and water from isobutyraldehyde and saturated aliphatic primary amines in aqueous solution at 35°:  $i\text{-PrCH=NMMe}$ , 4950;  $i\text{-PrCH=NEt}$ , 3490;  $i\text{-PrCH=NPr-}n$ , 4180;  $i\text{-PrCH=NBu-}n$ , 4040;  $i\text{-PrCH=NPr-}i$ , 1840;  $i\text{-PrCH=NBu-}i$ , 200. Two of the experimental methods used were based on ultraviolet measurements at the aldehyde and imine absorption maxima (at 2850 and about 2300 Å, respectively). These measurements gave satisfactory agreement with a pH method based on the fact that addition of isobutyraldehyde to primary amine buffers decreases the pH by transforming the amine to the much less basic corresponding imine. Largely on the basis of nuclear magnetic resonance data it is concluded that all the imines are very largely *trans* compounds and that in the principal conformations one of the carbon-methyl bonds of the isobutylidene group eclipses the carbon-nitrogen double bond. Both the nmr data and the equilibrium constants for imine formation may be rationalized semiquantitatively by the assumption that rotation around the carbon-nitrogen single bond so as to eclipse the carbon-nitrogen double bond with a carbon-hydrogen bond yields a conformation that is about 2.0 kcal/mole more stable than a conformation in which the carbon-nitrogen double bond has been eclipsed by a carbon-carbon bond.

ates, equilibria, and reaction mechanisms have been studied carefully in many reactions of the type

where  $\text{RNH}_2$  is a hydroxylamine or hydrazine derivative.<sup>3</sup> Several studies have also been made of the reactions of aromatic aldehydes with aromatic<sup>4</sup> and aliphatic amines<sup>5-8</sup> (and of the reverse reactions). Quantitative studies of the reaction in cases where R, R', and R'' are all hydrogen atoms or saturated alkyl groups are less common. In his review on imines, which covers their chemistry from the time of their discovery by Schiff in 1864 through Sept 1962, Langer describes no such studies.<sup>9</sup> Zuman reported the polarographic determination of the equilibrium constant for imine formation in the reaction of ammonia and several amino acids with pyruvic acid and several aldehydes and ketones,<sup>10</sup> and Březina and Zuman described a similar investigation of the reaction of cyclopentanone and cyclohexanone with ammonia, methylamine, glycine, and other aliphatic amines.<sup>11</sup> More recently Le Sueur, Lefebvre, and Coussement have studied the reaction of acetone with isopropylamine,<sup>12</sup> and Williams and Bender have studied the reaction of acetone with

methylamine.<sup>13</sup> We have not been able to find any measurements of the equilibrium constant for imine formation from a saturated aliphatic aldehyde and an aliphatic amine.

For this reason, as part of a study of reactions involving the formation of imines as intermediates,<sup>14</sup> we have investigated the formation of imines from several saturated aliphatic amines and isobutyraldehyde, an aldehyde whose equilibrium constant for aldolization is rather unfavorable<sup>15</sup> and whose aldol cannot undergo simple dehydration to an  $\alpha,\beta$ -unsaturated aldehyde.

## Determination of $K$

**Ultraviolet Measurements at the Aldehyde Maximum.** The addition of primary amines to aqueous solutions of isobutyraldehyde causes a decrease in the intensity of absorption at the aldehyde maximum (2850 Å). By measurements of the absorption at 2850 Å in the presence of known initial concentrations of isobutyraldehyde and amine, the equilibrium constant for the reaction

may be calculated.

If  $I$  is the concentration of imine,  $W$  the concentration of water,  $B$  the concentration of amine, and  $A'$  the concentration of isobutyraldehyde in the free (unhydrated) form

$$K' = IW/A'B \quad (1)$$

Isobutyraldehyde is about 30% hydrated at equilibrium in aqueous solution at 35°.<sup>16</sup> Inasmuch as equilibrium is quite rapidly established between the free aldehyde

and its hydrate,<sup>16,17</sup> it is convenient for many purposes to treat the equilibrium mixture of aldehyde and hydrate as a single substance. The total concentration of free aldehyde and hydrate may be referred to as the apparent aldehyde concentration and denoted  $A$ . The apparent equilibrium constant is then

$$K = IW/AB \quad (2)$$

where  $K$  is equal to  $K'A/A'$ .

The absorbance  $D$  of a solution containing aldehyde, amine, and imine may be expressed

$$D = A\epsilon_A + B\epsilon_B + I\epsilon_I \quad (3)$$

where the  $\epsilon$ 's are the respective extinction coefficients. Substitutions and rearrangement lead to the expression

$$A_0/(A_0\epsilon_A + B_0\epsilon_B - D) = 1/(\epsilon_A + \epsilon_B - \epsilon_I) + W/[KB(\epsilon_A + \epsilon_B - \epsilon_I)] \quad (4)$$

where  $A_0 = A + I$  and  $B_0 = B + I$ . The value of  $A_0$  is simply equal to the concentration of aldehyde added initially. The value of  $B_0$ , however, is equal to the initially added, titrimetrically determined concentration of amine minus the concentration of substituted ammonium ion (conjugate acid of the amine).

To use eq 4 for the determination of  $K$ ,  $\epsilon_A$  and  $\epsilon_B$  were determined by measurements on solutions containing only isobutyraldehyde or only amine. Then, for solutions containing various amounts of aldehyde and amine, absorbances ( $D$ ) were determined and values of  $A_0$  were calculated from the volumes and concentrations of the standard solutions that had been used. From this point the method of successive approximations was used. Values of  $B_0$  and  $B$  were estimated from data on the solutions used to prepare the equilibrium solution, from the approximate equation  $D = A\epsilon_A$  (the last two terms in eq 3 are relatively small), and from estimates of the concentration of ammonium ions based on the ionization constant of the amine and the concentration of isobutyric acid determined titrimetrically to be present in the isobutyraldehyde solutions used. A knowledge of the concentration of the ammonium ions is of even greater importance in the determination of  $K$  by ultraviolet measurements at the imine maximum and by pH measurements. Therefore the basis for the calculations will be treated in some detail here, using the formation of the N-methylimine as a specific example.

Everett and Wynne-Jones determined the acidity constant of the methylammonium ion in water at ionic strengths (due to potassium chloride) 0.05, 0.10, 0.15, 0.20, and 0.25  $M$  at  $10^\circ$  intervals from  $10$  to  $50^\circ$ .<sup>18</sup> Plots were made of the  $\log K_a$  values at each ionic strength (and also the values extrapolated to zero ionic strength) vs. temperature. From these plots, values of  $\log K_a$  at  $35^\circ$  at the various ionic strengths were determined and a plot of  $\log K_a$  vs. ionic strength at  $35^\circ$  made. At any desired ionic strength a value of  $\log K_a$  may be read off this plot and combined with the value of the ion-product constant of water at the same ionic strength<sup>19</sup> to give the ionization constant of methylamine.

The value of  $W$ , the water concentration, was calculated from the partial molar volumes of the amines used, which were determined by measuring the densities of amine solutions of known concentrations, and from the partial molar volume of isobutyraldehyde, which was assumed to be equal to the molar volume of the pure material. Except in the case of the measurements made using *t*-butylamine, where  $W$  was as low as 50.5  $M$ ,  $W$  was in the range 53.2–55.1  $M$  in all our reaction solutions.

In this manner we obtained the values (or first approximations of the values) required for a plot of  $A_0/(A_0\epsilon_A + B_0\epsilon_B - D)$  against  $W/B$ , using the  $D$  values obtained experimentally;<sup>21</sup> in some cases, where  $W$  was essentially the same for all points, the abscissa in the plot was  $1/B$  rather than  $W/B$ . According to eq 4, the intercept of the best possible<sup>22</sup> straight line through the points is equal to  $1/(\epsilon_A + \epsilon_B - \epsilon_I)$ , and  $K$  (or  $K/W$  in plots against  $1/B$ ) is equal to the intercept divided by the slope. From the preliminary value for  $K$  thus obtained, values of  $B_0$  and  $B$  were calculated with increased accuracy and the entire process for the calculation of  $K$  repeated until no further changes were found in the values obtained. In the later plots the best line was determined by the method of least squares.

This method for determining  $K$  was used for a careful study of the reaction of methylamine with isobutyraldehyde and for preliminary studies using other amines. From the final plot obtained in one run on methylamine the value  $4900 \pm 160$  was obtained.

**Ultraviolet Measurements at the Imine Maxima.** The decrease in absorbance at 2850 Å brought about by the addition of saturated aliphatic primary amines to aqueous solutions of isobutyraldehyde is accompanied by an increase in absorbance around 2300 Å. In hexane solution unsubstituted aliphatic aldimines have been reported to have absorption maxima around 2460 Å with extinction coefficients of about  $80 M^{-1} cm^{-1}$ .<sup>23,24</sup> On going to the more polar solvent, ethanol, these extinction coefficients increase somewhat and the maxima shift to around 2380 Å. The extinction coefficients of the imines at their absorption maxima in water are about ten times as large as the apparent extinction coefficient of the aldehyde at its maximum. For this reason the equilibrium constants for the formation of some of the higher imines of isobutyraldehyde, which separate from aqueous solution at the concentrations most suitable for measurements at the absorp-

(19) These values were obtained from the data listed by Harned and Owen.<sup>20</sup> Values for the ion-product constant of water ( $K_w$ ) in the presence of potassium chloride, sodium chloride, and sodium bromide are listed in terms of molalities. These values were converted to molalities and plotted against the square root of ionic strength. Inasmuch as the values obtained for the three different salts are identical, within the experimental uncertainty, up to an ionic strength of 0.06  $M$ , a single line was drawn through the three set of points. The use of this line is equivalent to the assumption that the substituted ammonium salts that are responsible for the ionic strength in our reaction solutions have the same effect on  $K_w$  that the three alkali-metal salts do at a given ionic strength. The highest ionic strengths used were about 0.015  $M$ .

(21) In all cases equilibrium was shown to be established in a much shorter time than had elapsed when our equilibrium  $D$  values were measured.

(22) The intercept cannot be smaller than  $1/(\epsilon_A + \epsilon_B)$ , a known quantity.

naximum for isobutyraldehyde, may be determined conveniently by measurements at the absorption maximum of the imines.

Although the extinction coefficients of the amines at 2300 Å are considerably smaller than those of the imines, the concentration of amine is often considerably larger than that of imine. For this reason it was convenient to use in the reference cell an amine solution of about the same strength as that in the sample cell, instead of using pure water as was done in the experiments at 2850 Å. When this is done the term in eq 4 must be replaced by  $B_0 - B'$ , where  $B'$  is the concentration of amine in the reference cell. In order to avoid working with negative numbers, the term is also multiplied by  $-1$  to give

$$-A_0\epsilon_A - (B_0 - B')\epsilon_B = 1/(\epsilon_I - \epsilon_A - \epsilon_B) + W/[KB(\epsilon_I - \epsilon_A - \epsilon_B)] \quad (5)$$

Eq 5 was used to determine  $K$  graphically by the method of successive approximations, as described in the preceding section. The necessary ionization constants and various ionic strengths were obtained from the literature for methylamine,<sup>18</sup> ethylamine,<sup>25</sup> *n*-butylamine,<sup>25</sup> and *t*-butylamine<sup>26</sup> (in the first four by interpolation between data at higher and lower ionic strengths) and determined in the present investigation for isopropylamine. The values of  $K$  determined from eq 5 are listed in Table I.

Table I. Equilibrium Constants for the Formation of Imines of Isobutyraldehyde and Primary Amines in Water at 35°

Primary amine	$K^a$	
	Ultraviolet measurements at imine maximum	pH measurements
$\text{EtNH}_2^b$	$5050 \pm 190$	$4910 \pm 110$
$\text{EtNH}_2$	$3560 \pm 170$	$3420 \pm 120$
$\text{PrNH}_2$	$4210 \pm 50$	$4140 \pm 70$
$\text{PrNH}_2$	$1830 \pm 20$	$1850 \pm 70$
$\text{BuNH}_2$	$4060 \pm 80$	$4010 \pm 40$
$\text{BuNH}_2$	$199 \pm 4$	

<sup>a</sup> These are the dimensionless equilibrium constants defined by eq 5, in which  $W$  is the actual molar concentration of water. <sup>b</sup> Ultraviolet measurements at the aldehyde maximum gave a  $K$  value of 160.

**Measurements.** When isobutyraldehyde is added to a primary amine-amine hydrochloride buffer the pH increases. It is plausible that this is due to the formation of some of the primary amine to aldehyde imine which is considerably less basic. Although we found no report of the determination of the ionization constant of an aliphatic aldimine, there are theoretical reasons why the  $\text{sp}^2$  nitrogen atom of an imine should be less basic than the saturated nitrogen atom of the corresponding amine. Furthermore, the available data on aromatic aldimines and on cyclic ketimines support the argument that aliphatic imines are significantly less basic than the corresponding amines. Cordes and Jencks, for example,

found that the ionization constants of substituted *N*-benzylidene-*t*-butylamines vary from  $5 \times 10^{-7}$  for the *p*-methoxy compound to  $2.5 \times 10^{-9}$  for the *p*-nitro compound.<sup>7</sup>

Bfezina and Zuman reported that the imines derived from methylamine and cyclohexanone and cyclopentanone have ionization constants of  $2.7 \times 10^{-8}$  and less than  $10^{-8}$ , respectively.<sup>11</sup> On the basis of data on related compounds it has been estimated<sup>14</sup> that the ionization constant of *N*-isobutylidene-methylamine is around  $10^{-7}$  or less. In comparison, typical unsubstituted saturated primary and secondary amines have ionization constants in the range  $4 \times 10^{-4}$  to  $1.5 \times 10^{-3}$ .

If it is assumed that the imine formed is protonated to a negligible extent, the effect of adding isobutyraldehyde to a primary amine buffer is to remove some of the amine and thus increase the ratio  $[\text{RNH}_2^+]/[\text{RNH}_2]$ . The concentration of amine present after the addition of isobutyraldehyde to an amine buffer may be expressed

$$[\text{RNH}_2] = \frac{[\text{RNH}_2]_0 [\text{RNH}_2^+]_0 [\text{OH}^-]_0 K_b^0}{[\text{RNH}_2^+]_0 [\text{OH}^-]_0 K_b} \quad (6)$$

where the subscript and superscript zeros refer to concentrations before the addition of aldehyde and the ionization constant at the initial ionic strength, and the concentrations and ionization constant after the addition of aldehyde are written without zeros. The concentrations of hydroxide ion are calculated from the observed pH's and the ion-product constant of water at the proper ionic strength.<sup>19</sup> The concentration of ammonium ions is equal to the sum of the buffer anion concentration and the hydroxide ion concentration. The concentration of imine may be expressed

$$I = (V_0/V)([\text{RNH}_2^+]_0 + [\text{RNH}_2]_0) - [\text{RNH}_2^+] - [\text{RNH}_2] \quad (7)$$

where  $V_0$  is the volume of buffer solution before the aldehyde solution is added and  $V$  is the volume afterwards. From eq 6 and 7 and the concentration of aldehyde known to have been added, the equilibrium concentration for imine formation may be calculated.

From 14 to 31 different measurements were made for each of the amines studied, with the ratio of amine to aldehyde added being varied by at least fourfold and the hydrogen ion concentration being varied by an even larger factor. The results obtained are listed in Table I. Preliminary measurements were made using *t*-butylamine, but the equilibrium constant for imine formation is so small that the pH changes observed were not large enough to permit reliable results to be obtained.

### Properties of *N*-Isobutylidenealkylamines

The various *N*-isobutylidenealkylamines were isolated from the reaction of isobutyraldehyde with the primary amine. The nmr spectra of the imines isolated are summarized in Table II.

The ultraviolet absorption spectrum of each of the imines isolated was measured in 2,2,4-trimethylpentane solution, and the spectra of three imines were measured in acetonitrile. The wavelength of the absorption maxima and extinction coefficients at the maxima thus obtained are listed in Table III. Also listed

Table II. Nmr Spectra of N-Isobutylidenealkylamines

are the extinction coefficients and absorption maxima determined in water by the measurements in which the equilibrium constants for imine formation were also determined. The increase in extinction coefficients and shift of the absorption maxima to shorter wavelengths noted on going from saturated hydrocarbons to the more polar solvent ethanol<sup>28</sup> also occur on going to acetonitrile and to the even more polar solvent, water.

Each of the imines studied had a strong absorption band in the infrared at  $1670 \pm 5 \text{ cm}^{-1}$  due to the carbon-nitrogen double bond. This is in agreement with several Raman observations<sup>27-29</sup> and with previous infrared studies.<sup>30,31</sup> Densities, boiling points, and refractive indices are listed in Table IV.

## Discussion of Results

The formation of an imine from an aldehyde and a primary amine almost undoubtedly involves the intermediate formation of an  $\alpha$ -hydroxyamine.<sup>8</sup>

It seems extremely unlikely that either of the two products shown would be formed to the complete exclusion of the other. Therefore, it seems probable that the equilibrium constants we have measured are for the formation of a mixture of imine and  $\alpha$ -hydroxyamine. Some of the methods we have used give little information as to the composition of this mixture. All the methods, as employed, give evidence that one molecule of aldehyde reacts with one molecule of primary amine to give one molecule of product, but this does not distinguish between imine and  $\alpha$ -hydroxyamine formation. In principle, a distinction could be based on the fact that a molecule of water is a by-product in the formation of imine but not in the formation of  $\alpha$ -hydroxyamine. In practice, however, the concentration of water in our reaction mixtures was never varied by so much as 10%, so this distinction cannot be made.

The determination of  $K$  by pH measurements is based on the assumption that a product is being formed whose basicity is negligible in comparison to that of the primary amine being studied. If this assumption is in error the values of  $K$  determined should show a tendency to decrease as increasing amounts of aldehyde are added to a given buffer. No such tendency may be seen in the experimental results. Evidence that imines should be relatively weakly basic has already been described.<sup>7,11,14</sup> However, it is not unlikely that  $\alpha$ -hydroxyamines are also significantly weaker bases than the primary amines from which they are formed. From Hall's correlation of the basicities of aliphatic amines<sup>23</sup> it may be estimated that an  $\alpha$ -hydroxy substituent will decrease the ionization constant of an amine by 50–100-fold. Such a decrease will be partially offset by the greater basicity (by about twofold) usually observed for secondary amines, compared to primary amines. Thus an  $\alpha$ -hydroxyamine would probably be a weaker base than the primary amine from which it was formed, and it might be so weak as to be protonated to a negligible extent in the presence of the primary amine buffer.

(32) H. K. Hall, Jr., *J. Am. Chem. Soc.*, 79, 5441 (1957).

ultraviolet measurements at 2850 Å showed that the product is formed that absorbs almost negligibly at this wavelength, a property that is at least as plausible for  $\alpha$ -hydroxyamine as for the imine. The measurements around 2300 Å, however, show that a product is formed with an absorption maximum and an extinction coefficient greater than  $120\text{ M}^{-1}\text{ cm}^{-1}$  at this wavelength. Such properties are quite unlikely for a saturated  $\alpha$ -hydroxyamine but are reasonable for an aldimine. Therefore, it seems that the product whose formation we are studying is an imine. Nevertheless, the spectral properties expected of our imines cannot be predicted with enough quantitative reliability to rule out the possibility that some  $\alpha$ -hydroxyamine may also be in our product mixtures in aqueous solution.

Our results may be summarized by stating that the equilibrium constant for the isobutylidenation of an amine is rather larger than those for ethylamine, propylamine, and *n*-butylamine, and the constants for the latter amines are more than twice as large as for isopropylamine, which is almost nine times as large as the constant for *t*-butylamine. This variation of equilibrium constants seems most plausibly explained by steric hindrance. Before discussing such hindrance, however, we should discuss the detailed structure of the imines we have studied.<sup>32a</sup>

In analogy with the extensive studies that have been made on olefins and carbonyl compounds<sup>33</sup> it would be expected that our imines would exist in a conformation in which the carbon-nitrogen double bond is eclipsed by the hydrogen atom, 1, or one of the methyl substituents of the isobutylidene group, 2. We would expect the

coupling constant between the  $\alpha$ -hydrogen of the isobutyl group and the hydrogen attached to  $\text{sp}^3$  carbon (Table II) in 1 to be intermediate between the 1.5 cps reported as characteristic for such *trans* coupling constants in analogous olefins<sup>34</sup> and the value estimated for such *trans* coupling constants in unsaturated aldehydes.<sup>35</sup> Although we have not found any directly relevant published data on imines, Leonard and Pukstelis found a coupling constant of 10.0 cps for the two corresponding hydrogen atoms of the isobutylidene group in N-2-ethylbutylidenepyrrolidene perchlorate,<sup>36</sup> where steric effects would be expected to cause the compound to exist principally in a conformation like 1. For conformation 2, where these hydrogens are *gauche* to each other, a value inter-

mediate between the olefin value 3.7 cps<sup>34</sup> and the aldehyde value  $-0.3\text{ cps}$ <sup>35</sup> would be expected. The assumption of coupling constants for the imines exactly halfway between those for the analogous olefins and aldehydes (9.2 and 1.7 cps for *trans* and *gauche* coupling, respectively) plus the observed values of  $J_{\text{BC}}$  ( $4.1 \pm 0.2\text{ cps}$ ) leads to calculation of a 29–35% content of conformation 1 and a 65–71% content of conformation 2 in the imines studied. In view of the uncertainty in *trans* and *gauche* coupling constants used, this estimate of the relative fractions of the two conformations present is not highly reliable. We feel that the presence of significant amounts of conformation 2 is rather well established, and the simultaneous presence of significant amounts of conformation 1 is probable. Although conformation 2 appears to be the more abundant conformation, this abundance is not necessarily any greater than would be explained by the fact that there are two methyl groups that can eclipse the carbon-nitrogen double bond (as in 2) but only one hydrogen atom that can.

There is good evidence that aldimines in which the carbon-nitrogen double bond is conjugated with one or more aromatic rings exist preferentially in the *trans* form<sup>37</sup> (by the *trans* form we refer to the isomer in which the isopropyl group from the aldehyde is *trans* to the R group of the amine). In the *cis* forms of such compounds there would be steric interference with the coplanarity required for the maximum resonance stabilization. For imines derived from saturated aliphatic aldehydes and amines, however, little convincing evidence as to the relative stabilities of the two forms seems to have been published. The high rate of formation and hydrolysis of the imines studied under the conditions of their preparation makes it seem likely that the more stable forms were obtained. Conformations 1 and 2 have been written as *trans* isomers because of several lines of evidence that our compounds are *trans* isomers and that they are more stable than the corresponding *cis* isomers. Even in the case of N-isobutylidenemethylamine, the imine for which the *cis* isomer should be least strained, it may be pointed out that with the analogous hydrocarbons, the 4-methyl-2-penten-2-ones, equilibration studies show that the *trans* isomer is about 1.2 kcal/mole more stable than the *cis* isomer at 55°. The differences in stability between the *cis* and *trans* isomers are probably larger in the case of the imines than in the case of the olefins. If we assume carbon-nitrogen single- and double-bond distances of 1.44 and 1.30 Å and a C=N-C bond angle of 116.9° as reported for N-methylenemethylamine,<sup>41</sup> a C-C=C angle equal to the C-C=C angle in propylene (124.3°),<sup>42</sup> and an  $\text{sp}^3$ -carbon- $\text{sp}^2$ -carbon bond distance of 1.501 Å, like that in propylene, an internuclear distance of 2.80 Å may be calculated for the two carbon atoms attached to  $\text{sp}^3$  carbon and  $\text{sp}^2$  nitrogen in the *cis* isomer of an aldimine. The same assumptions

**NOTE ADDED IN PROOF.** Dr. N. J. Leonard has kindly brought to our attention the similar conclusions concerning conformational and isomerization in imines reached by W. J. Musliner, Ph.D. thesis, University of Illinois, Urbana, Ill., 1965.

plus a 1.336-Å carbon-carbon double-bond distance, as in propylene, lead to an internuclear distance of 3.03 Å for the two carbon atoms attached to  $sp^2$  carbon and *cis* to each other in a *cis* olefin. The difference of 0.23 Å should be sufficient to make the *cis* imine considerably more destabilized (with respect to the *trans* isomer) than the corresponding *cis* olefin. It should also be noted that the difference in stabilities of the two geometric isomers of the 4-methyl-2-pentenes is related to the difference between an isopropyl-methyl *cis* interaction and an isopropyl-hydrogen *cis* interaction, whereas the difference in stabilities of the geometric isomers of our imines is related to the difference between an isopropyl-R *cis* interaction and an isopropyl-unshared pair *cis* interaction.

Furthermore, if our argument that there are significant amounts of both conformations 1 and 2 is correct, the relative amounts of these conformations and hence the magnitude of the  $J_{BC}$  values in Table II would be expected to vary markedly as the R group attached to nitrogen is changed from methyl through ethyl and isopropyl to *t*-butyl if any or all the imines studied existed to a significant extent as *cis* isomers. The essentially constant character of  $J_{BC}$  therefore provides evidence that the imines are practically all *trans*.

In none of our nmr spectra were extra bands that might have been expected from small amounts of *cis* isomer noted. This might be explained by the hypothesis that all the corresponding hydrogen atoms have the same chemical shifts in the two isomers, but nmr data on geometrically isomeric ketimines make this hypothesis implausible.<sup>43,44</sup> It might also be hypothesized that the *cis-trans* equilibrium is established so rapidly that the nmr spectra of the two isomers have become fused. However, this hypothesis, too, is implausible. A survey of data on rate of *cis-trans* isomerization of imines shows that all the N-alkyl compounds studied isomerize much too slowly for fusion of nmr spectra.<sup>44</sup> These data also show no detectable tendency for aldimines to isomerize more rapidly than analogous ketimines. Therefore it appears that our imines consist very largely of one isomer.

Yardley, Hinze, and Curl have shown that the carbon-nitrogen double bond in N-methylenemethylamine is eclipsed by one of the hydrogen atoms of the methyl group.<sup>45</sup> By analogy with this observation as well as with the studies on olefins<sup>33,34</sup> and carbonyl compounds,<sup>33,35</sup> we expect N-isobutyldenemethylamine to exist in a conformation like 3. We suggest

that with the imines derived from ethylamine, *n*-propylamine, and *n*-butylamine the conformation with an alkyl group in place of  $H_a$  is considerably less stable than the conformations in which the alkyl group

is in the place of  $H_b$  or  $H_c$ . It is true that such a conformation may be considered to be analogous to conformation 4 for 1-butene, which has been reported to be about as heavily populated as either of the other two conformations, of the type of 5.<sup>34</sup> However, the same

assumptions concerning molecular geometry made earlier in this section plus a 1.091-Å  $sp^2$ -carbon-hydrogen bond distance,  $120.5^\circ$   $H-C=$  bond angles (as in propylene),<sup>42</sup> 1.54-Å  $sp^2$ -carbon- $sp^3$ -carbon bond distances, and  $109.5^\circ$  bond angles around  $sp^3$  carbon lead to an internuclear distance of 2.06 Å between  $H_a$  and an  $sp^3$  carbon atom in the place of  $H_a$  in conformation 3, in contrast to a 2.39-Å distance between  $H_a$  and  $C_a$  in conformation 4. This difference of 0.33 Å seems large enough to explain the suggested difference in relative conformational stabilities. The imine derived from isopropylamine would have one relatively stable conformation (with methyl groups in the place of  $H_b$  and  $H_c$  of 3) and two unstable conformations (with one methyl group in the place of  $H_a$  and another in the place of  $H_b$  or  $H_c$ ). All three conformations of the imine derived from *t*-butylamine would be destabilized by interaction between  $H_a$  and a methyl group in the place of  $H_a$ .

The nmr spectra of the imines support these suggestions. There is good evidence that coupling constants between pairs of protons analogous to  $H_a$  and  $H_d$  (in olefins, for example) are much smaller than between pairs like  $H_b$  (or  $H_c$ ) and  $H_d$ .<sup>46</sup> It is therefore to be expected that  $J_{CD}$  is largest for the methylimine, smaller for the ethyl-, *n*-propyl-, and *n*-butylimines, and smallest for the isopropylimine.

The equilibrium constants for imine formation may be rationalized fairly satisfactorily in terms of steric effects alone if we assume that replacement of  $H_b$  or  $H_c$  in 3 by an alkyl group leads to a conformation with a free energy content 2.0 kcal/mole (at  $35^\circ$ ) lower than when  $H_a$  is replaced by an alkyl group. Then relative to an equilibrium constant of about 70 (one-third of the equilibrium constant for the formation of the *t*-butylimine) for the formation of an imine in a conformation with an alkyl group in place of  $H_a$  in 3, the equilibrium constant for the formation of an imine in a conformation that lacks this destabilizing feature should be about 1800. These two figures may be used to calculate the equilibrium constants for the formation of the various imines. For the methylimine, with three stable conformations, the equilibrium constant should be  $3 \times 1800$  or 5400; for the ethyl-, *n*-propyl-, and *n*-butylimines, with two stable and one unstable conformation, about  $(2 \times 1800) + 70$  or 3670; for the isopropylimine, with one stable and two unstable conformations, about  $1800 + (2 \times 70)$  or 1940; and for the *t*-butylimine, with three unstable conformations, about  $3 \times 70$  or 210. This assumed difference in conformational stabilities may also be used to calculate relative populations of conformations, which may be combined with

$-H_d$  type coupling constant of 0.2 cps and an  $i$  (or  $H_c-H_d$ ) coupling constant of 2.3 cps, calculate values of  $J_{CD}$  (Table II) of 1.6, 1.3, 1.3, 1.3, 4 cps for the methyl-, ethyl-, *n*-propyl-, *n*-butyl-, isopropylamines, respectively. Support for this variation of the  $J_{CD}$  values is found in the report of coupling constant of 1.6 cps between the methyl protons and the carbimino hydrogen of *N*-benzylamine<sup>47</sup> (which we assume to be *trans*), in the report of coupling constants in the range 1.8–2.1 cps between the carbimino hydrogens and the hydrogens bonded to nitrogen-bound carbon in the ring of *N*-eneopyrrolidinium salts<sup>36</sup> (where the relationship between the carbimino hydrogens is nearer to that between  $H_d$  and  $H_c$ ) than to that between  $H_d$  and  $H_a$  in 3), in the report of a coupling constant of about 1.5 cps between the *ortho*-faced hydrogen atoms in *t*-BuCH=NCH<sub>3</sub> (1.3 cps would be expected from our correlation), and in the reports of no coupling between the *ortho*-faced hydrogens of *t*-BuCH=NCHMeEt<sup>24</sup> and compounds of the type RCH=NCHRAr<sup>48</sup> (where steric effects should favor a conformation like 3). By analogy with observations on olefins<sup>46</sup> it is presumed these coupling constants ( $J_{CD}$ ) are negative.

Enough destabilization resulting when a primary group is put in place of  $H_a$  rather than  $H_b$  or  $H_c$  to form 3 provides a plausible rationalization of the observations, there is some uncertainty in the amount of 2 kcal/mole, postulated for the amount of this destabilization. The observed coupling constants could be related with any amount of destabilization that largely prevents alkyl groups from taking the place of  $H_a$  in 3; therefore they could be correlated satisfactorily with any amount of destabilization larger than about 1 kcal/mole. The existence of significant steric effects would indicate uncertainty in the amount of 2.0 kcal/mole, which is derived from an extension of the equilibrium constants solely in terms of steric effects. Part of the decrease in equilibrium constants observed in the series Me, Et, *i*-Pr, *t*-Bu could be attributed to decreased stabilization of the carbon–nitrogen double bond by hyperconjugation.<sup>48</sup> It is that polar effects can be important in imine formation, inasmuch as preliminary observations on the series in which the steric factor has been held essentially constant show that the Taft reaction constant is somewhat negative.<sup>1b</sup> However, in view of the generally negative substituent constants for the isopropyl, and *t*-butyl groups, it may be seen that steric effects would act so as to offset hyperconjugation.

Evidence against the major importance of hyperconjugation in the present case is provided by the observation that the largest change in log *K* occurs in the isopropyl and *t*-butyl cases. Hyperconjugation seems a poor explanation for most of this variation. In view of our nmr evidence that the isopropyl group exists very largely in a conformation in which the carbon–hydrogen bond is in a plane orthogonal to the  $\pi$  orbitals of the carbon–nitrogen double bond. In addition to the various effects on the stability of the imine being formed, the relative magnitudes of the equilibrium constants for imine formation may also be

influenced by effects on the relative stabilities of the amine reactants (that are not balanced by analogous effects on the relative stabilities of the imines). However, we have no evidence for the importance of such effects nor arguments that any such effects should be important. We therefore conclude that steric effects of the type postulated are the predominant factors in bringing about the observed variation in equilibrium constants for imine formation but that other factors are probably insignificant. A plot of log *K* vs. Taft's  $E_s$  values (acyl component)<sup>49</sup> gives a good straight line for the methyl, ethyl, isopropyl, and *t*-butyl compounds, but the equilibrium constants for the *n*-propyl- and *n*-butylimines are almost twice as large as they should be to fall on this line. Our rationalization of the data gives no explanation of why these two equilibrium constants are larger than the equilibrium constant for the formation of the ethylimine.

## Experimental Section

**Reagents.** The isobutyraldehyde and amines used were distilled and stored under nitrogen. The *N*-isobutylidenealkylamines were prepared from isobutyraldehyde and primary amines by a method based on that of Campbell, Sommers, and Campbell.<sup>50</sup> They were purified by distillation and stored under nitrogen. Their properties are listed in Tables II–IV.

**Instrumentation.** The ultraviolet spectra were determined using Cary recording spectrophotometers (Model 14). A Beckman Research pH meter (Catalog No. 101900) and glass and calomel electrodes were used for the pH measurements. The infrared spectra were determined with Perkin-Elmer spectrophotometers, Models 21 and 337. The nmr spectra were determined on the neat liquids using Varian A-60 spectrometers. Tetramethylsilane was used as an internal standard.

**Ionization Constant of Isopropylamine.** The acidity constant of isopropylammonium ions was determined by titration of aqueous solutions of isopropylamine potentiometrically with perchloric acid using a Beckman Research pH meter. The  $pK_a$  was calculated from the pH at half-neutralization with due allowance for the concentration of hydroxide ions, which was not negligible in comparison to the concentrations of amine and its conjugate acid. The titration container was thermostated at  $35 \pm 0.5^\circ$ . The acidity constant of the isopropylammonium ion was found to be 10.334, 10.309, 10.294, 10.265, and 10.231 at ionic strengths 0.0625, 0.0377, 0.0236, 0.0106, and 0.0030 *M*, respectively, and the value extrapolated to infinite dilution is 10.21. The most nearly comparable value listed in Perrin's compilation is a  $pK_a$  of 3.40 for isopropylamine at room temperature.<sup>51</sup> If "room temperature" was  $25^\circ$ , this corresponds to a  $pK_a$  of 10.60 for the isopropylammonium ion, from which a value of 10.28 at  $35^\circ$  may be calculated by use of Perrin's methods of correcting for temperature changes.<sup>52</sup> The agreement of this value with ours is as good as could be expected in view of the uncertainty in temperature. The agreement with de Ligny's  $pK_a$  of 10.15 for the isopropylammonium ion at  $25^\circ$ <sup>53</sup> is rather poor.

**Determination of Equilibrium Constants for Imine Formation.** The operations were carried out under nitrogen and solutions were made up using water from which the dissolved air had been replaced by nitrogen. In a typical experiment using the ultraviolet procedure, a volumetric flask was 95% filled with water, a weighed amount of isobutyraldehyde added, and the flask was filled to the mark with water. After the flask had been shaken a sample was titrated with standard base to determine the concentration of isobutyric acid present in the solution. Amine solutions were prepared similarly by weighing except in the case of the more volatile amines, the strength of whose solutions were determined by titration. When ultraviolet measurements were made on such solutions and their mixtures, water at  $35^\circ$  was circulated through the cell

# The *meso-dl* Isomerization of 2,3-Dimethyl-2,3-diphenylsuccinonitrile<sup>1</sup>

Laurence I. Peterson

Contribution from the Edgar C. Britton Research Laboratory,  
The Dow Chemical Company, Midland, Michigan. Received November 4, 1966

**Abstract:** The *meso* and *dl* diastereomers of 2,3-dimethyl-2,3-diphenylsuccinonitrile have been interconverted both thermally and photochemically. The equilibrium constant (*dl/meso*) is 1.22 and is relatively insensitive to temperature. From the rate of isomerization, studied in the 125–175° range, one calculates  $\Delta H^\ddagger = 42.4$  kcal/mole,  $\ddagger = 17$  cal/deg mole. The isomerization probably proceeds *via* the 1-phenyl-1-cyanoethyl radical,  $C_6H_5(CH_2)\dot{C}H-CN$ , as suggested by trapping experiments with thiophenol and with oxygen. The greater stability of the *dl* isomer, compared to *meso*, implies an attractive interaction between *gauche* cyano groups.

*Meso* and *dl* diastereomers of appropriately substituted ethane derivatives represent classical examples of stereoisomerism. It has been recognized some time that such configurational isomers are not only in their physical and chemical properties but also in their thermodynamic energy contents.<sup>2</sup>

In spite of the generally accepted energy differences in *meso-dl* systems, very few experimental data are available to support these conclusions. In fact, we cannot yet predict with any confidence which isomer is the more stable in even relatively uncomplicated tri- or hexasubstituted ethanes. Usually it is assumed that where strong intramolecular forces are present, the *dl* form is thermodynamically more stable than the *meso* and in the absence of such forces that the *meso* isomer is the more stable.

Although these statements are probably correct, the necessary limitations are not always observed. Unfortunately much of the experimental data which would support these statements is of a nature some of the existing and especially older data on relative isomer stabilities in these systems is misleading owing to difficulties and attendant errors in making structural assignments, determining isomer ratios, and establishing equilibrium constants.

The interconversion of *meso* and *dl* isomers has been observed in only a few isolated instances, and no conditions have been made on a related series of compounds. Of the conventional means for effecting isomerization, namely, thermal, photochemical, Lewis acid metal, and basic catalysis, only the latter methods have been employed to interconvert *dl* diastereomers in acyclic systems.<sup>3</sup>

Wittig and Spoerri have shown that *dl*-2,3-dimethyl-2,3-diphenylsuccinonitrile is partially converted to the *meso* isomer in the presence of aluminum chloride.<sup>4a</sup> A similar

study by Nenitzescu and Glatz<sup>4b</sup> suggests that the *meso* form may be the more stable. However, in both cases there remains some question as to whether equilibrium conditions prevailed. Buckles, *et al.*,<sup>7</sup> found that the presence of halogens effects the isomerization of *dl*- $\alpha,\alpha'$ -dibromobibenzyl and *dl*- $\alpha,\alpha'$ -dichlorobibenzyl to their *meso* forms. Solid *dl*- $\alpha,\alpha'$ -dibromobibenzyl upon standing in bromine vapor for an extended period reportedly was converted 90% to the *meso* isomer. It should be pointed out, however, that this may not truly reflect the relative free energy differences between the two isomers since crystal lattice forces may be the dominating influence.

*dl*-2,3-Dimethylsuccinic acid was found to be partially isomerized to the *meso* diacid upon prolonged treatment with acid, leading Linstead and Whalley to conclude erroneously that the *meso* isomer was the more stable.<sup>8</sup> Eberson<sup>9</sup> subsequently has shown that when the *dl*- and *meso*-2,3-dimethyl-, -2,3-diethyl-, and -2,3-diisopropylsuccinic acids are equilibrated with strong hydrochloric acid, the racemic forms predominate. The somewhat unexpected stability of the *dl* isomers was attributed to intramolecular hydrogen bonding between adjacent carboxyl groups. Recently, similar intramolecular interactions have been invoked to explain the predominance of *dl*-2,3-butanediol which arose from the treatment of *meso*-2,3-butanediol with sodium in toluene followed by hydrolysis.<sup>10</sup> *d*-Tartaric acid upon prolonged refluxing with aqueous potassium hydroxide gave a mixture of *dl* and *meso*-tartaric acid which yielded twice as much *dl* as *meso* upon isolation, however, only about half of the initial tartaric acid was recovered.<sup>2</sup>

Since polyphenylated ethanes are well known to dissociate thermally into polyphenylmethyl radicals, substitution of the phenyls by groups which also will weaken the central carbon-carbon bond either through steric or electronic forces and concurrently satisfy the necessary requirements for *meso* and *dl* isomerism should provide convenient systems for studying the phenomenon of *meso-dl* isomerization. Such compounds

presented in part at the 152nd National Meeting of the American Chemical Society, New York, N. Y., Sept 11–16, 1966.

are the isomeric *meso*- and *dl*-2,3-dimethyl-2,3-diphenylsuccinonitriles.<sup>11,12</sup> In these compounds, the steric interactions between the various groups are not of the magnitude present in hexaphenylethane, but each substituent is capable of stabilizing the resulting radical through inductive effects or by delocalization of the electron into a  $\pi$ -electronic system.

The present work concerns the study of the *meso*-*dl* isomerization of the diastereomeric 2,3-dimethyl-2,3-diphenylsuccinonitriles. The results which we now report give some new information with regard to *meso* and *dl* isomer stabilities, and an attempt has been made to clarify some of the factors which influence isomer stabilities in these systems.

## Results

When an *o*-dichlorobenzene solution of either the *dl* (I) or *meso* (II) isomer of 2,3-dimethyl-2,3-diphenylsuccinonitrile is heated at 150°, a mixture of the two forms is soon obtained. The isomerization is uncomplicated by potentially undesirable competing reac-

tions such as reaction with solvent molecules, disproportionation,<sup>13</sup> or ketenimine formation.<sup>14</sup> At equilibrium the *dl* isomer predominates with the *dl*/*meso* ratio being about 1.23 (55% *dl* and 45% *meso*). This isomer ratio corresponds to a free energy difference between the two isomers of 0.12 kcal/mole. As can be seen from Table I temperature has a negligible effect on the equilibrium constant.

Table I

Temp, °C	% <i>dl</i>	$k_{eq}$	$\text{—sec}^{-1} \times 10^5\text{—}$		$t_{1/2(meso)}$ , hr
			$k_{meso \rightarrow dl}$	$k_{dl \rightarrow meso}$	
125.0	55.3 $\pm$ 1.0	1.24 $\pm$ 0.05	0.186	0.153	103
150.0	54.9 $\pm$ 1.0	1.22 $\pm$ 0.05	4.11	3.53	4.7
175.0	55.0 $\pm$ 1.0	1.22 $\pm$ 0.05	64.5	55.4	0.30

No solvent effect was noted upon the *dl*/*meso* ratio when the isomerization was conducted in tetrachloroethylene, benzonitrile, and nitrobenzene. In all cases the *dl*/*meso* ratio was 1.22  $\pm$  0.05.

The *meso*-*dl* isomerization of I and II can also be effected photochemically at 25° by irradiating a benzene solution of either isomer at 2537 Å. Although the photostationary state has not yet been rigidly established, initial results suggest that the *dl*/*meso* ratio is about 1.0.<sup>15</sup>

(12) R. L. Huang and L. Kum-Tah, *J. Chem. Soc.*, 2570 (1954).

(13) 2,2,3,3-Tetraphenylbutane dissociates in solution to give 1,1-diphenylethyl radicals which subsequently disproportionate into 1,1-diphenylethane and 1,1-diphenylethylene. See K. Ziegler, *Ann.*, **551**, 127 (1942). Bartlett and McBride observed a similar disproportionation of 2,3,4,5-tetramethyl-3,4-diphenylhexane. At 100° they observed a disproportionation/combination ratio of 0.7.<sup>5</sup>

(14) Recombination of 2-cyanopropyl radicals produced in the thermal decomposition of azobisisobutyronitrile affords dimethylketenecyanoisopropylimine (33%) in addition to tetramethylsuccinonitrile (66%). See M. Taalt-Erben and S. Bywater, *J. Am. Chem. Soc.*, **77**, 3710 (1955).

(15) The isomer ratio obtained at equilibrium should not necessarily correspond to that observed at the photostationary state since the

The isomerization of I to II appears to proceed by homolytic scission of the central carbon-carbon bond to give methylphenylacetone radicals (III) which then recombine. The ratio of combination to disproportionation must be greater than 100 at 150° since no disproportionation products could be observed over ten half-lives. At 175°, however, after 100 half-lives (>30 hr) a disproportionation product was detected by nmr spectroscopy and gas chromatography, namely, methylphenylacetone (IV). The other product of disproportionation, 1-cyanostyrene (V), was not observed but this is not unexpected since 1,1-disubstituted olefins such as V polymerize readily. When the isomerization was studied in nitrobenzene at 150–160° a much larger amount of disproportionation was observed than in *o*-chlorobenzene (40% *vs.* 0% after 23 hr).

Evidence supporting the radical intermediate III was gained by conducting the isomerization in the presence of a good hydrogen donor. If *meso*-2,3-dimethyl-2,3-diphenylsuccinonitrile is dissolved in thiophenol and the solution heated to 170–180°, quantitative reduction to methylphenylacetone occurs within 2 hr. After only 1 hr in thiophenol, the *dl*/*meso* ratio of the remaining succinonitrile was 0.8 (*vs.* 1.22 at equilibrium), indicating that reduction proceeds at a rate comparable to that of isomerization. The fact that isomerization to the *dl* isomer is observed at all suggests part of the reaction may proceed within a solvent cage or that thiophenol is somewhat inefficient as a radical scavenger.<sup>16</sup>

Oxygen was also found to be a scavenger of methylphenylacetone radicals. When an *o*-dichlorobenzene solution of *meso*-2,3-dimethyl-2,3-diphenylsuccinonitrile was placed under 6 atm of oxygen at 175°, the slow formation of acetophenone was observed. The rate of acetophenone formation appeared to be much slower than the rate of isomerization since less than 10% of the succinonitrile was converted to acetophenone after 24 hr. Again, either a significant portion of the isomerization takes place within a solvent cage<sup>16</sup> or oxygen is a poor scavenger of methylphenylsuccinonitrile radicals. The latter explanation is consistent

former is thermodynamically controlled whereas the latter should not be. See G. S. Hammond, J. Saltiel, A. A. Lamola, N. J. Turro, J. S. Bradshaw, D. O. Cowain, R. C. Counsell, V. Vogt, and C. Dalton, *ibid.*, **86**, 3197 (1964).

(16) Experiments are in progress to determine the portion of the isomerization which occurs within the solvent cage. Preliminary results from crossover experiments suggest that the cage effects may be quite small.

ie results of Hartzler who found that the dimer- of dicyanobenzyl radicals was not apparently 1 by the presence of oxygen.<sup>17</sup> Although not d, the peroxide VI seems to be a likely inter- e which would be produced by the reaction of i with III. Thermal decomposition of VI pre- ly would produce acetophenone.<sup>18</sup>

tempts to observe the methylphenylacetone nitrile by electron spin resonance spectroscopy were uring. Even at temperatures up to 300° under ons where radicals have been observed in similar unds,<sup>18</sup> no esr signal was detected. A calcula- the equilibrium constant at 300° for dissociation dicals indicates the radical concentration would ut  $10^{-6}$  M, a value approaching the lower limits ection.

isomerization of the 2,3-dimethyl-2,3-diphenyl- nitriles is conveniently followed by nmr spec- py. The methyl protons of the two isomers t distinct resonance peaks which are separated 8 ppm. The methyl absorption of the *meso* occurs at  $\delta$  1.80 while that for the *dl* form is slightly downfield, at  $\delta$  2.08.

rates of the *meso*-*dl* interconversion were studied 0, 150.0, and 175.0  $\pm$  0.1° in *o*-dichlorobenzene ain the activation parameters for the reaction.

/*meso* ratios were determined periodically until rium was found to be established. The equi- were approach from both sides in each case. the data tabulated in Table II and treating the ization as a first-order reversible reaction, rate nts were obtained at each temperature for the sion of one isomer into the other (see Table I).

of the logarithms of the rate constants against iprocal of the absolute temperature gave good t lines (Figure 1). Since the equilibrium con- does not vary significantly with changes in tem- re, the activation parameters must therefore be the same for carbon-carbon bond scission in both s. The enthalpy of activation,  $\Delta H^\ddagger$ , was calcu- o be  $42.4 \pm 1.0$  kcal/mole and the entropy of ion was found to be about 17 eu.

much as the original structural assignments d for the isomeric 2,3-dimethyl-2,3-diphenyl- nitriles were based solely on the melting points two isomers, that of the *meso* being higher than the *dl*,<sup>12</sup> further characterization was necessary any conclusions could be drawn regarding relative stabilities. Both isomers were hydrolyzed, re, to their respective diacids; the *meso* diacid at 224°, while the *dl* diacid melted at 195–196° icipated (lit.<sup>19</sup> 196–197°). Thus the structural nents were confirmed since the *dl* diacid had isly been prepared in an optically active state.

itionally, both diacids upon heating to their g points yield anhydrides, the *meso* giving the ydride VII (mp 106–107°) and the *dl* affording the nhydride VIII (mp 159–160°). The nmr spectra anhydrides further support the structural as- nts since the methyl proton resonance in the

Figure 1. Plot of  $\ln k_{meso}$  and  $\ln k_{dl}$  vs. the reciprocal of the absolute temperature.

*trans* ( $\delta$  1.35) was found to be 0.47 ppm upfield from that for the *cis* isomer ( $\delta$  1.82,  $\text{CDCl}_3$ ). This difference in chemical shift is in accordance with that predicted by the shielding effect of the adjacent phenyl groups.<sup>20</sup>

## Discussion

In assessing the relative stability of *meso* and *dl* diastereomers as well as that of the related *erythro* and *threo* isomers, qualitative arguments based primarily on steric factors (nonbonded *repulsive* interactions) have been invoked to explain or predict the free energy differences. In nonpolar compounds where there are no strong attractive interactions (such as the hydrogen bonding present in *vicinal* diols) and therefore where all of the nonbonding interactions between neighboring substituents are essentially of a repulsive nature, the *meso* isomers have been claimed to be more stable than their *dl* counterparts.<sup>2,4</sup> Inspection of Newman projections will show how similar reasoning can be applied to the *meso*- and *dl*-2,3-dimethyl-2,3-diphenylsuccinonitriles.

I. D. Hartzler, *J. Org. Chem.*, **31**, 2654 (1966).

a similar peroxide has been proposed to intervene in the reaction a with 1,2-dimethoxy-1,1,2,2-tetraphenylethane to afford benzo- and methyl benzoate. See G. E. Hartzler, C. J. Bredeweg, and *ibid.*, **30**, 3119 (1965).

L. McKinzie and A. Ritchie, *Ber.*, **71B**, 643 (1938).

(20) D. Y. Curtin, H. Gruen, and B. A. Shoulders, *Chem. Ind. (Lon- don)*, 1205 (1958).

In the 2,3-dimethyl-2,3-diphenylsuccinonitriles,  $A$  values<sup>21</sup> can be used as a measure of the relative steric bulk of each substituent and indicate the order as being phenyl > methyl > cyano.<sup>21,22</sup> If the two isomers are considered in their most preferred conformations, where the phenyl groups are *anti* to one another, then the *gauche* nonbonded interactions can be expressed as follows

*gauche* interactions<sub>*d,l*</sub> =

*gauche* interactions<sub>*meso*</sub> =

The difference in nonbonded interactions between the two forms is then

$\Delta$ *gauche* interactions<sub>*d,l-meso*</sub> =

Since the crossed steric interactions between two substituents of unequal size are less than the sum of the interactions between substituents of like size (provided the interactions are purely repulsive in nature), the *meso* isomer would possess less pronounced steric factors and should be adjudged the more stable.<sup>4</sup> A more quantitative treatment of these interactions can be performed by assigning values to the *gauche* interactions which are expressed in eq 3. The *gauche*  $CH_3/CH_3$  (0.85 kcal/mole) and  $CH_3/CN$  (0.10 kcal/mole) interactions can be ascertained from the conformational energy difference between the axial and equatorial substituent on a cyclohexane ring.<sup>23</sup> The value of a *gauche*  $CN/CN$  interaction is probably less than the comparable  $CH_3/CN$  interaction, i.e., less than 0.1 kcal/mole. Insertion of these values in eq 3 indicates that the maximum difference in steric interactions between the *dl* and *meso* forms is then about 0.65 kcal/mole. This undoubtedly is a maximum value since we assumed the two isomers to be in their most preferred conformation. Inasmuch as the other possible conformations are also populated, but probably to a lesser extent,<sup>25</sup> the actual difference in steric interactions is probably less than the calculated value. In considering the other extreme case where there is completely free rotation, and all the conformations are populated to the same extent, one predicts that the steric interactions are the same in both isomers. In view of these extremes, the actual energy difference due to steric repul-

sions must be between 0.65 and 0 kcal/mole. Additionally, since the values for the *gauche* interactions were obtained from relatively rigid cyclohexane systems, the extension of these quantities to mobile, acyclic systems might introduce considerable error. Consequently, only the direction and not the magnitude of these effects have significance.

Recently it has been pointed out that in considering entropy differences between *meso* and *dl* forms, the *meso* isomer must be compared with the *dl* pair and not simply with one of the active isomers.<sup>26</sup> Since the *d* and *l* isomers are distinctly different species, the entropy change which results from mixing the two forms is  $R \ln 2$  and the free energy of the *dl* form is lowered with respect to the *meso* isomer by  $RT \ln 2$  due to the entropy of mixing. However, since the *dl* isomer (symmetry number of two) possesses a higher degree of symmetry than the *meso* isomer (symmetry number of unity), reduction of the rotational degrees of freedom in the *dl* form increases its free energy by  $RT \ln 2$ , thereby offsetting the entropy of mixing. Consequently, the *meso* and *dl* isomers are essentially equivalent entropy-wise, and the relative isomer stabilities are enthalpy controlled.<sup>27</sup>

The foregoing discussion of *gauche* steric interactions (enthalpy differences) in the two isomers predicts the *meso* form should be the more stable and is contradictory to the experimental data. A possible explanation of this discrepancy can be found if one assumes that some of the nonbonded interactions are attractive rather than repulsive. For example, if *gauche*  $CN/CN$  interactions give rise predominantly to attractive forces, then substitution of a sufficiently negative value for the *gauche*  $CN/CN$  term in eq 3 could more than offset the steric interactions which favor the *meso* isomer.<sup>28</sup> If this were the case, the sum of the nonbonded interactions would be represented by a negative value and the *dl* isomer would be adjudged the more stable form. Qualitatively, this result can also be ascertained from an inspection of the conformation of each isomer where attractive interactions between neighboring cyano groups might be most favorable (IX and X). The steric requirements imposed by the methyl and phenyl groups will obviously be more severe in conformation IX for the *meso* isomer than the comparable conformation for the *dl* form (X) due to the eclipsed or partially eclipsed phenyl groups.

Similar explanations involving nonbonded attractive forces, ascribed by some authors to London dispersion forces,<sup>29</sup> have been advanced to rationalize the predominance of the *cis* isomers resulting from the equil-

(21) S. Winstein and N. J. Holness, *J. Am. Chem. Soc.*, **77**, 5562 (1955).

(22) B. Rickborn and F. R. Jensen, *J. Org. Chem.*, **27**, 4606 (1962).

(23) One-half of the conformational energy difference between axial and equatorial forms of a methyl and a cyano substituent on a cyclohexane ring provides a good estimate of a *gauche* methyl/methyl and methyl/cyano interaction.<sup>24</sup> Since the conformational free energy difference between an axial and equatorial methyl group is 1.7 kcal/mole and that for cyano is 0.2 kcal/mole, then a *gauche* methyl/methyl interaction is about 0.85 kcal/mole and a *gauche* methyl/cyano is about 0.1 kcal/mole.<sup>21</sup>

(25) Nmr studies have shown that the *meso*- and *dl*-2,3-diphenylbutanes, -2,3-diacetoxybutanes, and -2,3-dibromobutanes reside in their most preferred conformation less than 70% of the time at room temperature, thus at higher temperatures the most preferred conformations would be occupied to even a lesser extent. See A. A. Bothner-By and C. Naar-Colin, *J. Am. Chem. Soc.*, **84**, 743 (1962); F. A. L. Anet, *ibid.*, **84**, 747 (1962).

(26) Reference 24, p 25.

(27) The entropy contribution from the differences in symmetry has been pointed out by a referee, and this offsetting term invalidates an earlier explanation<sup>1</sup> of the greater stability of the *dl* isomer.

(28) The literature indicates that *gauche*  $CH_3/CH_3$  and  $CH_3/CN$  interactions are both repulsive terms.<sup>21,22</sup>

(29) H. A. Stuart, *Physik. Z.*, **32**, 793 (1931).

of a variety of halogenated olefins including 1-propene,<sup>30</sup> 1,2-dichloroethylene,<sup>31</sup> and 1-butadiene.<sup>32</sup> London forces have also been to explain the anomalous conformational of some halogenated ethanes.<sup>33</sup>

istence of attractive nonbonded interactions the participation of the nitrile group is not mented. The predominance of the *cis* isomer equilibration of crotononitrile and 3-chloro-ole, however, may be indicative of this type of n.<sup>30</sup> Similarly, the greater stability of the *trans* conformation in 1,2-dicyano- the preponderance of *cis*-1,2,3-tricyanocyclo- in the base-catalyzed decarboxylation of 1,2,3-tricarboethoxy-1,2,3-tricyanocyclo- and the predominance of *cis*-1,2-dicyano- ne in the thermal dimerization of acrylonitrile could be explained by London dispersion between the vicinal cyano groups. Further ill be necessary to establish the substance appositions.

discussed earlier, the free energy differences *meso* and *dl* isomers is a function of the non-teractions between the various substituents. me, it is not yet possible to assess the effect direction or magnitude of a given substituent lative stability of such diastereomers. Only continuing investigation of a related series nd *dl* isomers will this information be forth- Such a study is in progress.

## Experimental Section

**Thermal Isomerization of *meso*- and *dl*-2,3-Dimethyl-2,3-dicyanobutene.** The *meso* and *dl* isomers of 2,3-dimethylsuccinonitrile were prepared according to the procedure of H. and Sosnovsky by the Cu(II)-catalyzed oxidative dimerization of methylphenylsuccinonitrile.<sup>11</sup> The pure isomers were obtained by fractional crystallization from methanol. The *meso* isomer melted at 224° and the *dl* at 146–147°. The nmr spectra of the *meso* isomer revealed no extraneous peaks (i.e., none of the *meso* isomer observed in the spectrum of the *dl* isomer, etc.). The *meso* isomer exhibits a methyl resonance peak at  $\delta$  1.80 and that of the *dl* isomer came at  $\delta$  2.08 (CDCl<sub>3</sub>).

Of each isomer (0.5 M) were prepared in *o*-dichlorobenzene. The *o*-dichlorobenzene solutions were placed in ampoules which were sealed under nitrogen and immersed in a temperature bath at the indicated temperatures. The ampoules were removed periodically and their nmr spectra were obtained at 80°. The relative areas of the methyl resonance peaks were determined by integration. Good reproducibility was obtained in all cases ( $\pm 2\%$ ). The data in Table II were used for the thermal isomerizations at 125.0, 150.0, and 175.0°.

The isomerization was approached from both directions at each temperature and the same equilibrium constants were obtained within experimental error. The rate constants shown in Table I were obtained from the experimental data by simulating the simple first-order reaction on an analog computer and then finding the best fit of the experimental points.

The isomerization was also studied as 0.5 N solutions in three

300.0	44.7	11.0	48.8		
		15.5	46.0		

other solvents at  $150 \pm 2^\circ$  for 3 hr. The following results were obtained (solvent, *dl/meso* ratio): tetrachloroethylene, 1.23; benzonitrile, 1.27; and nitrobenzene, 1.22.

**Photoisomerization of *meso*-2,3-Dimethyl-2,3-diphenylsuccinonitrile.** A benzene solution (100 ml) containing 0.20 g of *meso*-2,3-dimethyl-2,3-diphenylsuccinonitrile was irradiated in a quartz vessel for 17 hr at 40° with 2537-Å light from low-pressure mercury lamps (Rayonet photochemical reactor, Southern New England Ultraviolet Co.). The solvent was removed under vacuum at 30°. The nmr spectrum of the resulting solid revealed that isomerization had occurred and the *dl/meso* ratio was 0.60. Under the reaction conditions in the absence of light no isomerization takes place. The photoisomerization of the *dl*-2,3-methyl-2,3-diphenylsuccinonitrile to *meso*-*dl* isomer mixture has been effect in a similar manner.

**Reduction of *meso*-2,3-Dimethyl-2,3-diphenylsuccinonitrile in Thiophenol.** A thiophenol solution 0.5 M in *meso*-2,3-dimethyl-2,3-diphenylsuccinonitrile was prepared in an nmr tube. The tube was sealed and placed in a bath at 170–180°. The progress of the reaction was followed by nmr spectroscopy. After 1 hr 90% of the succinonitrile had been converted to methylphenylacetone and the *dl/meso* ratio of the remaining 2,3-dimethyl-2,3-diphenylsuccinonitrile was 0.8, indicating that equilibrium had not been reached. After 2 hr, all of the succinonitrile had been reduced to methylphenylacetone. The presence of the acetone was established by peak enhancement of its characteristic nmr spectrum and comparison of the glpc retention time with authentic methylphenylacetone.

**Isomerization of *meso*-2,3-Dimethyl-2,3-diphenylsuccinonitrile in the Presence of Oxygen.** *o*-Dichlorobenzene (1 ml) containing 25 mg of *meso*-2,3-dimethyl-2,3-diphenylsuccinonitrile was heated at 170° under 100 psi of oxygen for 24 hr. After this period of time, the *dl/meso* ratio of the remaining 2,3-dimethyl-2,3-diphenylsuccinonitrile was about 1.2 and a small amount of acetophenone (~5%) was detected by its glpc retention time and its methyl resonance peak in the nmr spectrum of the crude product.

**Hydrolysis of the *meso*- and *dl*-2,3-Dimethyl-2,3-diphenylsuccinonitriles.** Each dinitrile (0.50 g) was suspended in a solution of 4.0 ml of concentrated sulfuric acid and 4.0 ml of acetic acid in 4.0 ml of water. The resulting suspensions were heated at reflux for 24 hr. The reaction mixtures then were poured into 25 ml of ice water, and the precipitates were collected on filter pads. These solids were dissolved in 20 ml of a 2.5% aqueous solution of potassium hydroxide by heating on a steam bath. The diacids were precipitated upon acidification with dilute hydrochloric acid and recrystallized from benzene. The *meso* dinitrile gave a dicarboxylic acid which melted at 224–225° and the *dl* isomer afforded a diacid melting at 197–198°. The melting point of the *dl* isomer corresponds well with that reported previously (mp 196–197°) for the racemic pair.<sup>19</sup>

**Dehydration of the 2,3-Dimethyl-2,3-diphenylsuccinic Acids.** Both the *meso*- and *dl*-2,3-dimethyl-2,3-diphenylsuccinic acids lose water upon melting and form an anhydride.<sup>19</sup> The *meso* isomer affords *cis*-2,3-dimethyl-2,3-diphenylsuccinic anhydride, mp 106–107°, and the *dl* isomer yields the related *trans* anhydride, mp 159–160°. The nmr spectrum of the *cis*-anhydride revealed the methyl resonance peak at  $\delta$  1.82 and the *trans* form exhibits its methyl peak at  $\delta$  1.35 (CDCl<sub>3</sub>). The infrared spectra of both compounds exhibited strong absorption bands at 1870 and 1798 cm<sup>-1</sup> characteristic of anhydrides.

# The Effect of Pressure on Rate and Equilibrium in Nucleophilic Addition to Mesityl Oxide

Julian J. Scott and K. R. Brower

Contribution from the Department of Chemistry, New Mexico Institute of Mining and Technology, Socorro, New Mexico. Received February 6, 1967

**Abstract:** The rates of addition of water, methanol, ammonia, and thiophenol to mesityl oxide have been determined at various pressures up to 1360 atm, and the activation volumes derived therefrom. It is inferred that the transition state for acid-catalyzed hydration involves two water molecules. The addition-elimination equilibrium involving methanol has been approached from both sides, and the difference between forward and reverse activation volumes agrees with the measured volume of reaction. The acid-catalyzed addition of methanol appears to be mechanistically similar to that of water. The activation volume for addition of ammonia decreased by 8 ml/mole on change of solvent from water to methanol, and a zwitterionic transition state is postulated. The activation volume for thiophenoxide ion is surprisingly large and nearly independent of solvent composition. It is inferred that the carbon-sulfur bond is nearly complete in the transition state.

Although the mechanistic details of reactions involving addition to carbon-carbon double bonds have been intensively studied for several decades, there still are important questions unanswered, and recently some conclusions which once seemed firmly based have been thrown into doubt. It was long thought that the rate-determining step of acid-catalyzed hydration of simple olefins did not involve participation by water because the rate is approximately proportional to Hammett's acidity function,  $h_0$ ; but Baliga and Whalley<sup>1</sup> have shown that the activation volume is substantially negative, and the opposite conclusion now seems inescapable. The Zucker-Hammett hypothesis has been challenged on more general grounds by Bunnett<sup>2</sup> who proposes another method for demonstrating the kinetic participation of water in aqueous reactions.

In contrast to the behavior of simple olefins it has been reported that  $\alpha,\beta$ -unsaturated carbonyl compounds<sup>3</sup> have rates proportional to  $(H_3O^+)$  rather than  $h_0$ . It appeared to us that this case too might profitably be studied by determination of activation volumes, and to this end we have selected mesityl oxide as substrate. This well-behaved substance gives clean acid-catalyzed addition of water and alcohols as well as uncatalyzed addition of neutral or negatively charged nucleophiles. Furthermore, the position of equilibrium in the alcohol reaction permits rate measurement from either side. The possibility of using a single substrate for such a variety of reactions ought to justify a rather stringent interpretation of variations in activation volume.

The use of activation volumes in the study of reaction mechanisms has been amply reviewed,<sup>4</sup> and we will only briefly state the empirically validated principles. Reactions which on other grounds are thought to have a bimolecular rate-determining step involving no net change in the number of ionic charges are char-

acterized by activation volumes in the range  $-5$  to  $ml/mole$ .<sup>5</sup> Contrariwise, the simple bond-breaking processes have positive activation volumes of comparable magnitude.<sup>6</sup> If the rate-determining step involves any preceding step back to the "starting materials" (as defined by the rate law) involves ionization or neutralization of charges, the change in the electrostatic energy of solvent contributes a component of 25–45  $ml/mole$  per pair. The smaller value is for water, and the larger for organic solvents of low polarity. There is some evidence that ionization or deionization in the transition state can be detected by testing the dependence of activation volume on solvent polarity.<sup>7</sup>

## Results and Discussion

**Acid-Catalyzed Addition of Water.** The kinetic data for this reaction are listed in Table I. By dilatometry it was found that the over-all change in volume of the reaction system is  $-9$   $ml/mole$ , and the difference between the partial molar volume of product and reactants in pure water is also  $-9$   $ml$ . Both mesityl oxide and diacetone alcohol have considerable volumes of mixing with water ( $-7.5$   $ml/mole$  each) due to their influence on the structure of water,<sup>8</sup> but this effect could not be expected to vary during the activation process. We have taken the precaution of proving that it shows no over-all change. The volume of activation was determined to be  $-10$   $ml/mole$ . Since this figure considerably exceeds the final volume of hydration, we believe that the transition state has partial bonds to a water molecule and a hydronium ion, and that proton transfer is concerted with the formation of the new carbon-oxygen bond. The results are strikingly similar to those obtained with the hydrolysis of two square-planar platinum complexes<sup>9</sup> which had already been thought to coordinate with two water molecules in or prior to the rate-determining step.

Bell, Preston, and Whitney<sup>3</sup> investigated the kinetics of mesityl oxide hydration with various acid catalysts up to concentrations of 3  $M$  and their data have

= 8.3), but for  $\text{HCl}$  the curvature is pronounced. In such cases it is recommended to evaluate  $\omega^*$  for which  $\text{HCl}$  gives a value of  $-3.0$  as shown in Figure 2.

Figure 2. Determination of Bunnett's  $\omega^*$  parameter for the hydration of mesityl oxide. Plot of  $[\log k - \log (\text{HCl})]$  against  $\log a_{\text{H}_2\text{O}}$ .

Bunnett's table correlating  $\omega$  and  $\omega^*$  values with reaction mechanism is shown in Table II. It appears that the hydration of mesityl oxide proceeds by a con-

Table II. Mechanistic Interpretation of  $\omega$  and  $\omega^*$  Values

$\omega$	$\omega^*$	Function of water in the rate-determining step
-2.5-0.0		Is not involved
1.2-3.3	$< -2$	Acts as a nucleophile
$> 3.3$	$< -2$	Acts as a proton-transfer agent

certed proton transfer and nucleophilic addition. This is in complete agreement with a transition state consisting of the aggregate (mesityl oxide,  $\text{H}^+$ ,  $2\text{HOH}$ ) as deduced from the activation volume and the over-all volume of reaction.

Three conceivable transition states are illustrated below.

(i) Rate-determining proton transfer to the  $\alpha$ -carbon

(ii) Rate-determining proton transfer to the carbonyl oxygen

(iii) Rate-determining proton transfer at the oxygen of the attacking nucleophile, the substrate having been previously protonated

It is not possible to discriminate among these mechanisms by using either activation volumes or Bunnett's parameters. Bell, Preston, and Whitney<sup>8</sup> proposed transition state 1 for this reaction with a rate-determining step the same as for enol-keto transformation. However, a termolecular mechanism with a transition state similar to 2 has been widely accepted for the hydration of acetaldehyde.<sup>10</sup>

Bunnett has suggested that the number of water molecules involved, that is, molecules of water able to affect reaction rates, can be correlated with  $\omega$  values, one  $\omega$  unit corresponding to one molecule of water. For this reaction  $\omega$  values of 5 and 8 imply that 5–8 water molecules are involved, but the activation volume can be accounted for by only two molecules provided the interaction is strong. It is difficult to think of an operational test for the diffuseness of solvent participation in view of the fact that the water molecule oscillators are coupled by H bonding.

**Acid-Catalyzed Addition of Methanol.** The reversibility of the addition of methanol to mesityl oxide allows measurement of the effect of pressure on the equilibrium constant as well as the forward and reverse rates. The data are given in Table III. By plotting the logarithm of the equilibrium constant against pressure in accordance with the relation

$$RT(\partial \ln K / \partial P)_T = -\Delta V \quad (1)$$

we obtain a value of  $-11$  ml/mole for the volume of reaction. The same value was obtained by subtracting the sum of the molar volumes of methanol and mesityl oxide from that of 4-methoxy-4-methyl-2-pentanone. By direct measurement the activation volume is  $-23$  ml/mole for the forward reaction and  $-13$  ml/mole for the reverse. The difference should be equal to the volume of reaction according to the principle of microscopic reversibility, and the agreement is satisfactory.

It is worthy of note that the reverse (elimination) reaction cannot be a simple unimolecular decomposition of the conjugate acid of the ether in enolic form as shown below, else the activation volume would almost certainly be positive. The values of both the forward

Table III. Kinetic and Equilibrium Data for Methanol-Mesityl Oxide System

and reverse activation volumes point to a transition state containing two methoxy moieties and analogous in structure to 1, 2, or 3.

**Addition of Ammonia.** The kinetic data for this reaction are given in Table I. The volumes of activation were  $-14$  ml/mole in water and  $-22$  ml/mole in methanol. The volume of reaction, measured dilatometrically, was  $-9$  ml/mole.

The variation of activation volume with solvent polarity indicates a polar transition state.

A dissection of the activation volume into separate components for solvent and reactant molecules may be attempted with the knowledge that the partial molar volumes of a variety of univalent electrolytes are 18–20 ml smaller in methanol or ethanol than in water.<sup>11</sup> If the relation between volume and polarization is assumed to be linear, the charge separation is 0.42 e; and if parabolic, 0.65 e. Since the volumes of ionization of acids and bases in water are about 25 ml/mole, the solvent component for our reaction in water would amount to  $25 \times \frac{2}{10} = 10$  ml, leaving 4 ml to be accounted for by contraction of the reactants along the carbon–nitrogen bond axis. Recalling that the volume of reaction is  $-9$  ml/mole, we may infer that the new bond of the transition state is approximately half-formed on both the geometrical and electrical scales.

**Addition of Thiophenol.** Thiophenoxide ion is the nucleophile for this addition, and reaction mixtures consisted of solutions of mesityl oxide, thiophenol, and sodium methoxide or hydroxide in the molar proportions 4:5:1. The kinetic data are given in Table I. The volume of activation was  $-20$  ml/mole in methanol

(10) Y. Pocker, *Proc. Chem. Soc.*, 17 (1960).

(11) S. D. Hamann and S. C. Lim, *Australian J. Chem.*, 7, 329 (1954).

19 ml/mole in a mixture of ethanol-water (55:45 v/v). A change in the amount of solvent electro-lyte might have been expected since a negative charge is being transferred from the thiophenoxide ion to the carbonyl oxygen and therefore becomes somewhat reduced. Since no significant change was observed, we ascribe the entire 19–20 ml to the formation of the carbon-sulfur bond. The volume of reaction observed in the dilatometer was –22 ml/mole, and it is thus that the transition state lies very close to product in the reaction coordinate. If this is so, it is understandable that the activation volume showed no change on going to solvent.

## Experimental Section

**Reagents.** Mesityl oxide and diacetone alcohol were prepared by the method of Vogel.<sup>12</sup> Mesityl oxide was distilled in the range 100–105°C (648 mm). The methyl ether of diacetone alcohol was prepared by the method of Lorette<sup>13</sup> using Dowex 50 as an acidic resin catalyst. Ammonia solution in methanol was prepared by heating a concentrated solution of ammonium hydroxide with the ammonia gas over calcium oxide and into methanol. The thiophenol was Eastman White Label grade. The solvent was Van Waters and Rogers 99.8% grade, and the ethanol was U.S.P. reagent quality.

**Dilatometry.** The over-all volume changes were measured with a dilatometer of 17.5 capacity with a capillary of 1 mm. The dilatometer was weighed before and after the reaction period to ensure that volume changes were not caused by evaporative loss. The rates of mixing of mesityl oxide and diacetone alcohol were determined by measuring the densities of the pure components and the density of the mixture. Concentrations used were the same as those used in the determination of the volume of activation. The volumes of mixing are somewhat dependent on concen-

**Methods of Kinetic Measurement.** Addition of water, methanol, and ammonia were followed by the disappearance of mesityl oxide as determined spectrophotometrically<sup>3</sup> employing the ion peak at 243 mμ for which  $\epsilon = 1.10 \times 10^4$ . A Beckman DU spectrophotometer, using a hydrogen lamp as an ultraviolet source, was employed for absorbance measurements. Rate constants for the addition of water were determined from a plot of the logarithm of concentration of mesityl oxide against time. Both forward and reverse rate constants for the addition of ammonia were determined from the expressions

$$K = k_f/k_r \quad (2)$$

$$\ln (c_0 - c_\infty)/(c - c_\infty) = k_f[c_0 t/(c_0 - c_\infty)] \quad (3)$$

the solution of the rate equation

$$dc/dt = -k_f c - k_r(c_0 - c) \quad (4)$$

$c_0$  = initial concentration of mesityl oxide,  $c_\infty$  = equilibrium concentration of mesityl oxide, and  $c$  = concentration of mesityl oxide at time  $t$ . Equilibrium constants at various pressures were determined from the ratio of the percentage of mesityl oxide converted to the percentage remaining.

Second-order rate constants for the addition of ammonia were determined from the expression

L. I. Vogel, "A Textbook of Practical Organic Chemistry," 3rd ed., Interscience, New York, 1961, pp 351–353.  
J. B. Lorette, *J. Org. Chem.*, **23**, 937 (1958).

$$1/(b - a) \ln [a(b - x)/b(a - x)] = k_f t \quad (5)$$

which is the solution of the rate equation

$$dx/dt = k_f(a - x)(b - x) \quad (6)$$

where  $x$  = decrease in concentration of mesityl oxide,  $a$  = initial concentration of mesityl oxide, and  $b$  = initial concentration of ammonia. Kinetic data for this addition were obtained from solutions that had reacted up to 40% completion. The reverse reaction was disregarded due to the high percentage conversion (88%) at equilibrium.

Rate constants for the addition of thiophenol were determined from a plot of the logarithm of concentration of mesityl oxide against time. The mesityl oxide concentration was obtained from the relation

$$c_{mo} = c_{mo}^0 - (c_{SH}^0 - c_{SH}) \quad (7)$$

where  $c_{SH}^0$  is the initial titratable thiophenol (includes thiophenoxide) concentration and  $c_{SH}$  is the titratable thiophenol at time  $t$ .

Titration was done potentiometrically with a Beckman Zero-matic pH meter, using a silver electrode, against a standard silver nitrate solution. The initial mesityl oxide concentration was determined spectrophotometrically. The rate constant obtained is pseudo first order and includes the thiophenoxide concentration term which remains constant

$$d(c_{SH})/dt = k c_{mo} c_{SH} \quad (8)$$

$$= k' c_{mo} \quad (9)$$

**Sampling Technique.** The sampling technique was basically the same for all the addition reactions. Aliquots totalling 5 ml were pipetted into a 6-ml, narrow-necked test tube, and mercury was added so that the solution filled the test tube. The tube was then inverted into a larger test tube; the two tubes were sealed by adding more mercury, and the larger one was filled with water and placed in the pressure vessel. After a suitable reaction time, usually longer than 3 hr, a 3-ml aliquot was removed for analysis. Considerable dilution was necessary for the determination of mesityl oxide concentrations spectrophotometrically owing to its very large extinction coefficient at 243 mμ. Dilutions were adjusted so that absorbance measurements of around 0.500 were obtained.

**Experimental Error.** The error in the volume of activation is due almost entirely to the uncertainty in the term  $\ln k_p/k_1$ . From duplicate rate measurements this uncertainty is from 4 to 8% and hence activation volumes obtained are accurate within the range of  $\pm 1.0$  to  $\pm 1.6$  ml/mole. Temperatures were controlled to within 0.05°C and pressures within 7 atm. Uncertainty in the reaction time was rendered negligible by having sufficiently long reaction times, usually from 3 to 4 hr. From duplicate measurements the uncertainty in the over-all volume changes is about 5%.

**Calculation of Activation Volumes.** The logarithm of the ratio of the rate constant at pressure to the rate constant at 1 atm ( $k_p/k_1$ ) was plotted against pressure, and the best straight line was drawn through the origin and the other points. The slope was used to evaluate the activation volume according to the equation

$$RT(\partial \ln k/\partial P)_T = -\Delta V^\ddagger \quad (10)$$

None of the plots had any obvious curvature, and this seems surprising in only one case, the addition of ammonia with methanol as solvent. Ion-producing reactions in organic solvents often show curvature at pressures as low as 1000 atm.<sup>4</sup>

Mechanisms of Ester Hydrolysis in Aqueous Sulfuric Acids<sup>1</sup>Keith Yates and Robert A. McClelland<sup>2</sup>*Contribution from the Department of Chemistry, University of Toronto, Toronto 5, Ontario, Canada. Received November 3, 1966*

**Abstract:** The rates of acid-catalyzed hydrolysis of methyl, *n*-propyl, isopropyl, *sec*-butyl, benzyl, phenyl, *p*-nitrophenyl, and *p*-chlorophenyl acetates have been investigated over a wide range of acidity (10–90% aqueous H<sub>2</sub>SO<sub>4</sub>) by means of spectrophotometric methods. First-order kinetics were obtained in every case, and the rate constants show one of three types of acid dependence, varying with ester structure: (i) a rate maximum at intermediate acidities followed by very slow hydrolysis in very concentrated acids; (ii) a rate maximum at intermediate acidities followed by a sharp increase in rate in very concentrated acids; and (iii) a continuous increase in hydrolysis rate with increasing acid concentration, becoming very rapid even at moderate acidities. These different rate–acidity dependences have been treated uniformly as a function of *H*<sub>0</sub> and the water activity to yield reaction parameters which are explicable in terms of a change in mechanism at some intermediate acidity for each ester, either from A<sub>Ac</sub>2 to A<sub>Al</sub>1 or from A<sub>Ac</sub>2 to A<sub>Ac</sub>1, depending strongly on ester structure.

The kinetic response of ester hydrolysis to changes in acidity has been investigated mainly in the dilute acid region where the information to be gained about detailed mechanisms is quite limited. This is chiefly because one important reaction variable, the water concentration (or activity), remains effectively constant. More detailed mechanistic information has come from the classical O<sup>18</sup>-exchange studies of Bender<sup>3</sup> and others. This work was also confined to the dilute acid region, and while extremely valuable, this approach does not always permit unequivocal decisions about reaction mechanisms. Although a few ester hydrolyses have been studied in more concentrated acids,<sup>4,5</sup> no systematic investigation of the dependence of hydrolysis rate on acid concentration has yet been made for esters. We therefore thought it of interest to investigate the variation of hydrolysis rate for simple esters over as wide a range of acid concentrations as possible, in the hope of obtaining further detailed information about the various possible mechanisms and under what conditions they occur. Of the four mechanisms possible for acid catalysis, namely the A<sub>Ac</sub>1, A<sub>Ac</sub>2, A<sub>Al</sub>1, and A<sub>Al</sub>2 mechanisms,<sup>6</sup> it is generally believed that apart from a few special cases, all ordinary esters hydrolyze by the A<sub>Ac</sub>2 pathway. The few clearly recognized exceptions such as *t*-butyl esters and mesitoates which are believed to hydrolyze by the A<sub>Al</sub>1 and A<sub>Ac</sub>1 mechanisms, respectively,<sup>7</sup> occur because of special structural factors in the ester. It is therefore of interest to investigate to what extent combinations of changes in structure, acidity, and water activity can lead to different mechanisms of hydrolysis even for ordinary esters.

## Results and Discussion

The esters chosen for study were all acetates, so that the effect of varying one structural parameter at a time

could be investigated. These were the methyl, propyl, isopropyl, *sec*-butyl, benzyl, phenyl, *p*-chlorophenyl, and *p*-nitrophenyl esters. Ethyl acetate was not investigated since rate data covering the entire range of sulfuric acid concentrations have been reported for this ester. The rate of hydrolysis of each was measured at 25° in aqueous sulfuric acid solutions covering as wide a range as possible. The acid used was limited in some cases by high reaction rates or by sulfonation reactions in the more concentrated region. Simple first-order kinetics were obtained in every case, acid concentration being effectively constant during each run, and the pseudo-first-order rate constants obtained for all eight acetates are listed in Table I. Each rate constant is the mean of at least two, and sometimes three or four independent determinations. It can be seen from these results that several of the esters exhibit local rate maxima at intermediate acid concentrations (50–60% H<sub>2</sub>SO<sub>4</sub>), similar to those previously reported<sup>11</sup> for amide hydrolysis occurring at much higher acid strengths. The rate dependence on acid concentration is quite different for the various types of ester; it can be seen clearly by plotting rate profiles of *k*<sub>1</sub> vs. % H<sub>2</sub>SO<sub>4</sub> as shown in Figure 1. Literature values<sup>9,10</sup> for the hydrolysis of acetate have been included in Figure 1 for comparison. The rate–acidity profiles obtained clearly belong to one of three types. Type i is characterized by a steady increase in rate with acid concentration, passing through a maximum at about 50–60% acid, followed by a rate decrease almost to zero by 80% acid and a final modest rate increase in the 85–100% range. Very similar behavior of this type is obtained for the three primary alkyl esters, as shown in Figure 1. Type ii behavior, shown by the secondary alkyl and benzyl esters, exhibits a rate maximum similar to type i at about 50–55% acid, but this is followed by a very sharp increase in rate well before the rate has approached zero. The acid region in which this sharp rate increase occurs depends markedly on the structure of the ester. Type iii differs from the previous two in having a

servable rate maximum, the rate increasing monotonically with acid concentration until the reaction is too rapid to follow by conventional methods even at moderate acidities. The three phenyl esters exhibit this type of behavior as shown in Figure 1, as well as *t*-butyl acetate. The reported data based on hydrolysis in HCl solutions<sup>13</sup> has been plotted for the *t*-butyl ester since as yet we have not been able to obtain satisfactory or reproducible results for any tertiary alkyl esters in sulfuric acid, partly because of their high reactivities and partly because of solubility problems.

It seems clear from the above diversity of behavior that all these esters cannot be reacting by the same mechanism, and further that changes in mechanism are

(12) P. Salomaa, *Suomen Kemistilehti*, B32, 145 (1959).Figure 1. Rate-acidity dependence for the hydrolysis of acetates in aqueous sulfuric acid at 25° (*k*<sub>1</sub> is the pseudo-first-order rate constant in min<sup>-1</sup>).

occurring for individual esters at different acidities. This raises three questions. First, can all of these rate profiles be explained in a way consistent with the types of mechanism previously mentioned? Second, can all these different rate-acidity dependences be treated quantitatively by some uniform approach, and finally can this be used to obtain any detailed information about the possible transition states?

We have shown previously<sup>13</sup> that rates of organic reactions in concentrated acids can be treated quantitatively as a function of the acidity and water activity of the reaction medium by an approach which is essentially a modification of the Bunnett hydration parameter treatment.<sup>4,14</sup> The modification involves basing the acidity of the reaction medium on an acidity function which is strictly appropriate to the type of substrate whose mechanism is being considered. For example, if we write the general rate scheme for ester hydrolysis in terms of fully hydrated species as

the following simple relationship between rate, acidity, and water activity can be derived from transition-state theory

$$\log k_1 + H_S = r \log a_{\text{H}_2\text{O}} + (\text{constant}) \quad (1)$$

(where *k*<sub>1</sub> is the pseudo-first-order rate constant) providing *H*<sub>S</sub> is an acidity function based on the ionization of indicators which are esters of the type whose hydrolysis reaction is being considered. The approxima-

tions and assumptions involved in obtaining eq 1 are then much less drastic than in the Bunnett hydration parameter treatment<sup>6,14</sup> and have been discussed previously.<sup>12</sup> If eq 1 is valid for ester hydrolysis, plots of  $(\log k_1 + H_S)$  should be linear in  $\log a_{H_2O}$  with a slope  $r$  which would give information about the involvement of water in the rate-determining step, and hence about the mechanism.

An equation like (1) has been found to give linear plots with uniform slopes for a number of amide hydrolyses<sup>13</sup> for which an amide-based acidity function is available<sup>15</sup> but as yet no ester-based acidity function such as  $H_S$  has been established. It would clearly be tedious and in some cases difficult if not impossible to establish an acidity scale strictly appropriate to each substrate type which is of interest, but fortunately this is not necessary, at least for acetate esters. Theoretically, the relationship between measured ionization ratios for esters and some suitable function  $H_S$  is given by

$$\log [SH^+]/[S] = -H_S + pK_{SH^+}$$

We have measured ionization ratios spectrophotometrically for several acetates whose rates of hydrolysis are not too fast in the acid range of interest and find that these closely obey the linear relationship

$$\log [SH^+]/[S] = -mH_0 + (\text{constant})$$

using available<sup>16</sup>  $H_0$  data. The slopes  $m$  are approximately 0.62 for simple acetates, which correspond closely to Lane's reported<sup>5</sup> value of 0.65 for the indicator slope of ethyl acetate. Therefore, we can use available  $H_0$  data to approximate to  $H_S$  by means of the relationship  $H_S = mH_0 + (\text{constant})$  and thus modify eq 1 to give

$$\log k_1 + mH_0 = r \log a_{H_2O} + (\text{constant}) \quad (2)$$

(15) K. Yates, J. B. Stevens, and A. R. Katritzky, *Can. J. Chem.*, **42**, 1957 (1964).

(16) M. J. Jorgenson and D. R. Hartner, *J. Am. Chem. Soc.*, **85**, 878 (1963).

Figure 3.  $\log k_1 + mH_0$  vs.  $\log a_{H_2O}$  for methyl, ethyl, and  $n$ -propyl acetates.

That this is a valid approximation to  $H_S$  can be shown by plotting all available acidity functions for sulfuric acid, namely the  $H_R$ ,<sup>17</sup>  $H_A$ ,<sup>18</sup>  $H_0$ ,<sup>19</sup> and  $H_1$ <sup>18</sup> functions, against the  $H_0$  function. Over a very wide range of acidity (more than eight logarithmic units) each of these functions is linear in  $H_0$  as shown in Figure 2, and, therefore, from the measured ionization behavior of the esters it is reasonable to conclude that the  $H_S$  function will vary with acid concentration approximately as shown in Figure 2.

We have tested the relationship in eq 2 using all of the rate data listed in Table I along with independently measured values of  $H_0$ ,  $m$ , and  $\log a_{H_2O}$ .<sup>20</sup> This is shown in Figure 3 for methyl, ethyl, and  $n$ -propyl acetates. Excellent linearity is obtained over a very wide range (0–80% acid) with an almost identical slope ( $r = 2.1$ ) for the ethyl and  $n$ -propyl esters and a very similar slope ( $r = 1.92$ ) for methyl acetate. In each case, a break occurs at about 80–85% acid, followed by an equally linear relationship, but with a small negative slope ( $r \approx -0.02$ ) which extends to very high acidities<sup>21</sup> or very low water activities. The same treatment of the data for the secondary alkyl acetates is shown in Figure 4. Again a linear relationship with  $r = 2.1$  is found for each ester over almost as wide a range of acid (0–70%) followed by a change to a different linear dependence with negative slope in the high acidity region. However, the break occurs earlier, and the final negative slope is steeper ( $r = -0.6$ ) for the secondary esters than for the primary. Very similar behavior to that of the

(19) R. L. Hinman and J. Lang, *ibid.*, **86**, 3796 (1964).

(20) W. F. Giauque, E. W. Hornung, J. E. Kunzler, and T. R. Rubin, *ibid.*, **82**, 62 (1960).

(21) At the higher acidities the fraction of total ester protonated becomes significant and the function plotted against  $\log a_{H_2O}$  is actually  $\log (h_0/h_1 + K_{SH^+})$ . Values of  $K_{SH^+}$  have been estimated from spectrophotometric measurements for methyl,  $n$ -propyl, and isopropyl acetates. Since these and the previously reported<sup>4</sup> value for ethyl acetate show little variation with structure and the slopes  $r$  are not sensitive to small changes in  $K_{SH^+}$  a value of  $K_{SH^+} = -7.2$  was adopted for the other esters.

Log  $k_1 + mH_0$  vs.  $\log a_{H_2O}$  for isopropyl, *sec*-butyl, and benzyl acetates.

For esters is obtained for benzyl acetate, also in Figure 4. The initial slope is about the same ( $\approx 2.0$ ), but the break occurs even earlier, at  $\approx 50\%$  acid. There are insufficient data to obtain a slope for benzyl acetate, but comparison with data for the secondary acetates shows this is very similar in its water activity dependence. The data for the three phenyl esters are plotted in Figure 5. This time the initial linear portion is  $\approx 0-50\%$  acid but again with initial slope  $\approx 2$ , followed by a fairly wide change-over  $\approx 50-70\%$ , and finally a small negative slope ( $\approx -0.2$ ) for *p*-nitrophenyl acetate at higher acidities. A substituted phenyl ester cannot be studied at low acidities because of sulfonation. Thus, each ester obeys eq 2 with a large positive slope initially, then changes over a wide range of acidity. This is followed by a marked change in water activity dependence at some higher acidity and presumably a new mechanism. Since the position and type of

change is not the same in every case, the new mechanism operating at high acidities is different for the primary alkyl and phenyl esters from that for the secondary alkyl and benzyl esters. However, the close similarity of the water activity dependence for all esters at low acidities strongly suggests that the same mechanism is operating in all cases. However, one clear exception to this kind of behavior is shown, not surprisingly, by *t*-butyl acetate. The limited data available for HCl solutions show that the water activity dependence for this ester is decidedly negative even in the most dilute acids. The few points available for this ester give  $r \approx -1.5$ .

The calculated hydration parameters are summarized in Table II. The least-squares correlation coefficients and  $\sigma_p$  values show that the statistical fit of the data to eq 2 is surprisingly good. This indicates strongly that

the assumptions and approximations involved in the present hydration parameter treatment are reasonably valid. The concentration ranges over which linearity is obtained are also surprisingly wide, particularly since average hydration numbers for all species involved must be steadily decreasing as the water available for hydration is decreasing with acid concentration.

The values of  $r$  obtained in different acid regions can be reasonably interpreted in terms of hydrolysis mechanism as follows. Regions where  $r \approx 2$  (low acidities for all esters except *t*-butyl) correspond to hydrolysis by an  $A_{Ac}2$  type of mechanism in which a protonated ester molecule is attacked in the rate-determining step by two water molecules, one acting as a nucleophile and the second assisting in dispersing the positive charge developing on oxygen in the transition state I as progress is made toward the tetrahedral intermediate II

The second water molecule is then in a position to accept a proton in the formation of the intermediate II. Lane has previously suggested<sup>8</sup> that two water molecules are involved in the transition state for ethyl acetate hydrolysis, but possibly in a cyclic structure III rather than that shown in I, but there appears to be no compelling reason to prefer either structure. On the basis of theoretical calculations of medium effects on

hydrolysis rates Laidler<sup>22</sup> has concluded that for simple esters the transition state contains a molecule of ester, a hydronium ion, and a water molecule. This is consistent with either I or III in that over-all two water molecules plus a proton plus ester are involved. However, Laidler suggests a transition-state structure which differs in detail from either of the above.

Regions where  $r$  becomes negative but is fairly close to zero (i.e.,  $r \approx -0.2$ ) correspond to changes from the  $A_{Ac}2$  to the  $A_{Ac}1$  mechanism, in which ester conjugate acid undergoes unimolecular fission to acylium ion and alcohol. Water is essentially not involved in the rate-determining step, hence the water activity dependence is effectively zero.<sup>23</sup> This behavior occurs for the

(22) K. J. Laidler and P. A. Landskroener, *Trans. Faraday Soc.*, **52**, 200 (1956).

(23) That  $r$  is not actually zero probably reflects the fact that  $\alpha_{H_2O}$  slopes in the higher acid regions cannot be interpreted as quanti-

primary alkyl and phenyl esters. Although the methyl, ethyl, *n*-propyl, phenyl, and *p*-nitrophenyl esters must all form the same acylium ion if they react *via* the  $A_{Ac}1$  mechanism the change in water activity dependence occurs much earlier for the three phenyl esters. This is reasonable since cleavage to form acylium ion would be assisted more by the electron-withdrawing phenyl groups than by alkyl groups, so that this new mechanism can occur before the available water has been as drastically depleted as in the very high acid concentrations required before the primary alkyl acetates change mechanism. In agreement with this is the fact that at low acidities the rates of hydrolysis are in the order phenyl > *p*-chlorophenyl > *p*-nitrophenyl, but by about 75% acid (where  $A_{Ac}1$  predominates) this order is exactly reversed. Although the data are limited, the log  $\sigma$  values for the phenyl esters give reasonably good linearity with  $\sigma$  in each of the acid ranges studied. Below 55% acid the  $\rho$  value is close to  $-0.2$  in each of several acids, but above 70% acid it becomes  $+0.5$ . This change in both the sign and magnitude of  $\rho$  is consistent with a changeover from an  $A_{Ac}2$  to  $A_{Ac}1$  type of mechanism.

Regions where  $r$  is negative but significantly less than zero ( $r \sim -0.5$ ) also correspond to a "unimolecular" fission of protonated ester, but by the  $A_{Al}1$  mechanism. The strong negative water activity dependence indicates that water is actually being released in the rate-determining step, which is reasonable for decomposition of a strongly hydrated ester conjugate acid to give a weakly hydrated carbonium ion, especially since *t*-butyl acetate is known to hydrolyze  $A_{Al}1$  and also has a substantial negative water activity dependence in HCl. It has already been pointed out<sup>24</sup> that  $r$  values obtained in very concentrated acids cannot be interpreted too quantitatively but it seems reasonable that  $t < p$  for a reaction leading to a carbonium ion and a neutral molecule.

This behavior is shown by the isopropyl, *sec*-butyl, and benzyl esters in the higher acid regions. The regions where  $r$  becomes negative for these esters are also consistent with the expected order of stability of the carbonium ions formed in  $A_{Al}1$  hydrolysis, i.e., *t*-butyl (dilute) > benzyl (65%) > *sec*-butyl (75%) > isopropyl (80%).

That the sign of  $r$  should actually change in going from an  $A_{Ac}2$  to an  $A_{Al}1$  or  $A_{Ac}1$  mechanism is in general agreement with Whalley's<sup>24</sup> conclusions based on the pressure dependence of hydrolysis rates. For  $A_2$  type hydrolyses,  $\Delta V^{\ddagger}$  is found to be significantly negative, whereas for  $A_1$  type hydrolyses  $\Delta V^{\ddagger}$  is either zero or has a small positive value.

tatively as those for lower acidities since the approximations inherent in eq 2 will be less valid at higher acidities.

reasons for the characteristic rate-acidity plot obtained for various types of ester can now be sized in terms of structure, acidity, and water. These are shown schematically in Figure 6 for *t*, secondary, tertiary, benzyl, and phenyl esters and the water activity variation of the medium superimposed. Primary alkyl esters show an initial rate increase due to protonation of an increasing fraction of ester, until reduction of available water slows the "bimolecular" process. Eventually the rate goes to 0 as  $a_{\text{H}_2\text{O}} \rightarrow 0$ , until at extremely high acidities acylium ions can be formed. Despite the fact that the mechanism does not require water, this final rate increase is modest owing to the difficulty of forming the acylium ion. Secondary alkyl esters show an initial rate increase passing through a maximum at intermediate acidities for similar reasons. However, as  $a_{\text{H}_2\text{O}} \rightarrow 0$  and  $V \rightarrow 0$  a new mechanism can occur which does not require available water. As this unimolecular ion mechanism predominates the rate increases sharply since secondary carbonium ions are easier to form than acylium ions. For tertiary alkyl esters the rate rises rapidly with acidity even in the intermediate acid region due to the ease of formation of carbonium ions. The benzyl ester resembles the secondary alkyl type, except that the mechanism changes from  $A_{\text{Ac}}2$  to  $A_{\text{Ac}}1$  earlier because of the intermediate stability of benzyl carbonium ion. The phenyl ester is somewhat unusual in showing no rate maximum at intermediate acidity, after an initial rate increase resembling those for primary and secondary alkyl esters. Since the rate continues to increase sharply at very low values of  $a_{\text{H}_2\text{O}}$  a unimolecular mechanism must be taking over. Since phenyl carbonium ion is extremely unlikely, the new mechanism must be  $A_{\text{Ac}}1$ . The reason this occurs as low as 70% sulfuric acid has been discussed previously. In conclusion it seems clear that even simple esters can hydrolyze by a variety of mechanisms and that extreme acidities are not necessary before  $A_{\text{Ac}}1$  type mechanisms can occur. The present quantitative treatment of ester hydrolysis rates appears promising. It would be interesting to apply this treatment to other catalyzed reactions whose detailed mechanisms are not well understood. The *r* values could then be established as a useful indicator of mechanism, in addition to those already available from  $\text{O}^{18}$ -exchange studies, kinetic isotope effects, and stereochemical studies, particularly since taken individually these criteria do not always allow unambiguous conclusions to be drawn.

## Experimental Section

**Materials.** Commercially available acetates were either distilled before use or recrystallized from methanol-water. Acids below 95% (w/w) were prepared by diluting CIL grade acid (95% min) and more concentrated acids by this acid with Fisher reagent fuming (30%) acid. Acid concentrations were determined by titrating weighed samples with standard base. The  $H_0$  values of these solutions were by interpolation from a graph of the data of Jorgenson et al.<sup>14</sup>

**Methods.** The method chosen for each ester depended on ultraviolet absorption characteristics of the ester itself and the acid solution of interest. In some cases both methods were used suitably.

*n*-butyl, *n*-propyl, isopropyl, and *sec*-butyl acetates in sulfuric acid above 25%, and for phenyl, *p*-chlorophenyl, and *p*-nitro-

phenyl acetates in all acids, the change in ultraviolet absorption was measured using a Perkin-Elmer Model 350 spectrophotometer with either repeated scanning attachment or external recorder. The wavelength range 182–195  $m\mu$  (1-mm cells,  $\text{N}_2$  purging) was used for the alkyl acetates and the range 260–280  $m\mu$  (1-cm cells) for the phenyl acetates. This method could not be used below 200  $m\mu$  for solutions in the low acidity range because of the background absorption due to hydrogen sulfate ion.<sup>15</sup> The cell compartment was thermostated at  $25 \pm 0.2^\circ$ . Concentrations of ester used depended on solubility and extinction coefficient and were generally in the range 0.02–0.2 *M* for the alkyl and  $10^{-3}$  to  $10^{-4}$  *M* for the phenyl esters. Excellent linear plots of  $\log A$  vs. time were obtained in all cases (correlation coefficients  $\geq 0.999$ ), and the pseudo-first-order rate constants obtained using different wavelengths near the maximum for a given ester were in good agreement. The results of a typical run using this technique are given in Table III.

**Table III.** Kinetic Data for the Hydrolysis of Isopropyl Acetate at  $25^\circ$ ; Sulfuric Acid Concentration, 65.2%; Initial Ester Concentration, 0.238 *M*.

<sup>a</sup> Absorbance measured at 191  $m\mu$  using 1-mm cells.

For benzyl acetate, and for the alkyl acetates in acids below 25% and *n*-propyl acetate above 85% acid, the following modification of the method of Jaques<sup>16</sup> was used. Sulfuric acid (50 ml) of known concentration and ester (0.02–0.04 ml) were mixed in a reaction vessel thermostated at  $25.0 \pm 0.1^\circ$ . At suitable time intervals, 5-ml samples were withdrawn and poured onto crushed ice. These were then neutralized, first with concentrated, then with 0.1 *N* sodium hydroxide to exactly pH 7. This neutral solution was made up to 100 ml with distilled water and a 20-ml aliquot added to 10 ml of 2 *M* hydroxylamine hydrochloride and 10 ml of 2.5 *N* sodium hydroxide. After 10 min, 5 ml of 5.6 *N* HCl was added followed by an excess of 15% ferric chloride in 0.2 *N* HCl. The optical density of this solution at 540  $m\mu$  was measured within 2 min on a Bausch and Lomb Model 505 spectrophotometer using 10-cm cells. Accurate pH control (1.0–1.4) is required in the above procedure to prevent hydrolysis of the ferric chloride complex of the acethydroxamic acid formed from unreacted ester. This method also gave good linear plots of  $\log(\text{ester})$  vs. time from which the pseudo-first-order rate constants were obtained.

**pK Determinations.** The indicator behavior of methyl, *n*-propyl, and isopropyl acetates was investigated by measuring the zero-time extinction coefficient at 190  $m\mu$  as a function of sulfuric acid concentration. The data were treated by standard methods and for methyl acetate fitted the equation  $\log [\text{BH}^+]/[\text{B}] = 0.63(-H_0 -$

<sup>a</sup> Zero-time extinction coefficient measured at 190 m $\mu$ . <sup>b</sup> Calculated from the equation  $\log [\text{BH}^+]/[\text{B}] = 0.62(-H_0 - 7.16)$  with  $\epsilon_{\text{B}} = 65$ ,  $\epsilon_{\text{BH}^+} = 598$ ,  $g_{\text{B}} = -14.7$ ,  $g_{\text{BH}^+} = 0$ .<sup>26</sup>

7.25), and for *n*-propyl acetate the equation  $\log [\text{BH}^+]/[\text{B}] = 0.62(-H_0 - 7.18)$ . A typical set of experimental data for *n*-propyl acetate is given in Table IV. This was treated by a previously described<sup>26</sup> method to obtain the best fit of the experimental points

to a calculated curve based on the equation  $\log [\text{BH}^+]/[\text{B}] = m(-H_0 - pK)$ . The above method of obtaining *m* values was preferred over the more conventional logarithmic plots for two reasons. First, the  $\log [\text{BH}^+]/[\text{B}]$  vs. *H*<sub>0</sub> plots only utilize data obtained within a narrow range, usually 1.5–2.0 *H*<sub>0</sub> units either side of *pK*, whereas the previously described kinetic treatment using *m* involves data obtained over a much wider acidity range (15–98% sulfuric acid). Second, both the linearity and slopes of these log plots can be influenced by medium effects on the spectra of the base and conjugate acid forms. The present method reduces the seriousness of this possibility by correcting for medium effects. Unfortunately the rate of hydrolysis of isopropyl acetate is too high in acids above 90% to obtain reliable zero-time extinction coefficients. However, below this acidity, plots of  $\log \epsilon$  for isopropyl and *n*-propyl acetates against *H*<sub>0</sub> are strikingly similar, and it is reasonable to assume that the ionization behavior of isopropyl acetate closely resembles that of the *n*-propyl ester. Lane,<sup>8</sup> using a similar method, found the ionization behavior of ethyl acetate in sulfuric acid followed the equation  $\log [\text{BH}^+]/[\text{B}] = 0.65(-H_0 - 6.93)$ . The close similarity of the indicator slopes and “*pK*” values for methyl, *n*-propyl, and ethyl acetates indicates that the protonation behavior of acetate esters is reasonably independent of structure. For the other acetates studied no reliable protonation data could be obtained either because of too rapid hydrolysis or because sulfonation interfered at the high acidities required to measure  $\epsilon_{\text{BH}^+}$ . Therefore, in cases where no indicator slope could be measured, a value of *m* = 0.62 was assumed, and an approximate *pK* of -7.2 was used to correct for fraction protonated, where necessary.<sup>21</sup>

## Stable Carbonium Ions. XXXIV.<sup>1</sup> The 1-Methylcyclopentyl Cation<sup>2</sup>

George A. Olah, J. Martin Bollinger,<sup>2a</sup> Chris A. Cupas, and Joachim Lukas<sup>2b</sup>

Contribution from the Department of Chemistry, Case Western Reserve University, Cleveland, Ohio 44106. Received February 10, 1967

**Abstract:** 1-Methyl-1-chlorocyclopentane, cyclopentylcarbonyl chloride, and cyclohexyl fluoride (chloride, bromide) in  $\text{SbF}_5\text{-SO}_2$  solutions at  $-60^\circ$  gave a stable solution of the 1-methylcyclopentyl cation. The same ion is also formed when 1-methylcyclopentanol or cyclohexanol were dissolved in  $\text{FSO}_3\text{H-SbF}_5$  solutions. 1-Methylcyclopentene and cyclohexene are protonated in  $\text{HF-SbF}_5\text{-SO}_2$  or  $\text{FSO}_3\text{H-SbF}_5\text{-SO}_2$  solution to the 1-methylcyclopentyl cation, which is also formed by hydride abstraction from methylcyclopentane and cyclohexane in  $\text{FSO}_3\text{H-SbF}_5$  solution. The structure of the 1-methylcyclopentyl cation was investigated based on its nmr spectrum.

The acid-catalyzed isomerization of methylcyclopentane and cyclohexane has long been recognized and studied and has provided much useful information concerning the carbonium ion chain mechanism for hydrocarbon isomerization.<sup>4,5</sup> In terms of product

stability, cyclohexane is favored. The equilibrium mixture at  $25^\circ$  consists of 77% cyclohexane and 23% methylcyclopentane.<sup>6</sup> In terms of carbonium ion stability, however, the tertiary methylcyclopentyl cation I should be favored over the secondary cyclohexyl cation II. No good estimate is available concerning either the relative energy differences between these two

(6) A. L. Glasebrook and W. G. Lovell, *J. Am. Chem. Soc.*, **61**, 1717 (1939), reported in accordance with ref 2 that the equilibrium mixture at  $25^\circ$  consists of 77% cyclohexane and 23% methylcyclopentane. D. P. Stevenson and J. H. Morgan, *ibid.*, **70**, 2773 (1948), found the equilibrium favors cyclohexane at lower temperatures, the amount of methylcyclopentane increasing with temperature.

the activation energy necessary for their interconversion.

In the course of the investigation of stable carbonium acidic solvent systems like  $\text{SbF}_5$  or  $\text{SbF}_5\text{-FSO}_3\text{H}$ , it is of interest to attempt the observation of the cation ions formed from both 1-methylcyclopentyl and cyclohexyl precursors. We briefly reported on the formation of 1-methylcyclopentyl cation I in 1963,<sup>2</sup> and would like now to present in detail our observations regarding this ion.<sup>3</sup> As ion I was observed to be formed from a variety of precursors in strong acid, its investigation also proved interesting with respect to applying a variety of methods in its generation.

### Experimental and Discussion

In 1-chloro-1-methylcyclopentane (1) was dissolved in  $\text{SbF}_5\text{-SO}_2$  solution at  $-60^\circ$  a stable solution of ion I was obtained. Ion I was also obtained from cyclohexylcarbinyl chloride (2) or cyclohexyl chloride (3) (fluoride, bromide) in the same solvent at  $-60^\circ$ . The primary cyclopentylcarbinyl cation and the secondary cyclohexyl cation thus rearrange with great ease at  $-60^\circ$  to the tertiary ion I which is the only cation observed by nmr spectroscopy.

Using  $\text{FSO}_3\text{H-SbF}_5$  as the acid medium, 1-methylcyclopentanol-1 (4) and cyclohexanol (5) gave also ion I. 1-Methylcyclopentene-1 (6) and cyclohexene (7) were also protonated in  $\text{HF-SbF}_5\text{-SO}_2$  or  $\text{FSO}_3\text{H-SbF}_5\text{-SO}_2$  at  $-60^\circ$  to give I. Furthermore, we observed that the extremely strong acid  $\text{FSO}_3\text{H-SbF}_5$  can affect hydride ion abstraction from 1-methylcyclopentane (8) or cyclohexane (9) to form ion I.<sup>3</sup> Table I summarized the different precursors and pathways leading to ion I.

The pmr spectrum of the methylcyclopentyl cation at  $-60^\circ$  is shown in Figure 2. The substantially deshielded methyl ( $-3.98$  ppm) and  $\alpha$ -methylene ( $-4.50$  ppm) protons adjacent to the positive charge bear the anticipated positions.<sup>10</sup> Particularly noteworthy is the long-range coupling ( $J_{\text{H-H}} = 4.0$  cps) of the methylene and methyl hydrogens through the  $\text{sp}^2$ -hybridized center of ion I. Similar long-range coupling is observed in simple alkylcarbonium ions. Thus

as in previous papers of this series.

M. Brouwer and E. L. Mackor [*Proc. Chem. Soc.*, 147 (1964)] observed the methylcyclopentyl cation and claimed, based on NMR, that above  $-20^\circ$  the methyl group shifts along the ring, not in concert with this explanation and feel that line broadening is due to other reasons.

The application of  $\text{FSO}_3\text{H-SbF}_5$  as a hydride-abstracting medium to generate carbonium ions from hydrocarbon is a general method: see Olah and J. Lukas, *J. Am. Chem. Soc.*, 89, 2227 (1967).

The dimethylethylcarbonium ion (*t*-amyl cation) observed in NMR, the positions of the methyl and methylene groups adjacent to the positive charge are at 4.50 and 4.93 ppm: G. A. Olah, E. B. C. Evans, W. S. Tolgyesi, J. S. McIntyre, and I. J. Bastien, *J. Am. Chem. Soc.*, 86, 1360 (1964).

Figure 1.

Figure 2.

in the dimethylethylcarbonium ion (*t*-amyl cation) (III),  $J_{\text{H-H}} = 5.0$  cps,<sup>10</sup> while for the dications IV and V,  $J_{\text{H-H}} = 3.0$  and 4.0 cps, respectively.<sup>11</sup> The  $\beta$ -methylene protons at  $-2.47$  ppm show also the anticipated deshielding. Finally, quenching ion I in methanol at  $-70^\circ$  gave a high yield (80%) of 1-methylcyclopentyl methyl ether<sup>12</sup> with smaller amounts of methylcyclopentene.

The fact that, starting from either 1-methylcyclopentyl or cyclohexyl precursors even at  $-60^\circ$ , we were able to observe only the 1-methylcyclopentyl cation indicates that rearrangement of any initially formed cyclohexyl cation occurs too rapidly to be detected by nmr, at least under the experimental conditions used in the present work. Although the exact mechanistic details of this rearrangement are not yet known, we favor a mechanism not involving the intermediacy of a primary carbonium ion, which would represent a substantially high energy barrier. A rearrangement mechanism similar to the one proposed by Nenitzescu,<sup>13</sup> involving

a protonated cyclopropane intermediate, merits consideration.

## Experimental Section

All compounds with the exception of 1-chloromethylcyclopentane and 1-methylcyclopentyl methyl ether were commercially available. 1-Chloro-1-methylcyclopentane was prepared by the procedure of Merrwein and Mühlendyk.<sup>14</sup> 1-Methylcyclopentyl methyl ether was prepared according to the method of Lutz, *et al.*<sup>15</sup>

**Nmr Spectra.** The nmr spectra were obtained on a Varian Associates Model A56-60A spectrometer equipped with a variable-temperature probe. All spectra were run at  $-60^\circ$ . The chemical shifts are recorded in parts per million relative to external TMS.

**Preparation of Solutions of 1-Methylcyclopentyl Cation. a. From Halides.** A saturated solution of antimony pentafluoride in sulfur dioxide was prepared (at  $-10^\circ$ ). Portions (2 ml) of this solution were cooled to  $-78^\circ$ , causing some antimony pentafluoride to crystallize from solution. To this suspension was added

with stirring approximately 0.2 g of the appropriate 1-methylcyclopentyl or cyclohexyl halide. Slight warming was required to complete the ionization, whereupon a homogeneous solution resulted with only slight traces of color. Ion concentrations were around 10%.

**b. From Alcohols.** The precursor alcohol (1-methyl-1-cyclopentanol or cyclohexanol) in  $\text{SO}_2$  was cooled to  $-60^\circ$  and added to a vigorously stirred 1:1 molar mixture of  $\text{FSO}_3\text{H}$  and  $\text{SbF}_5$  at  $-60^\circ$ . Generally an excess of  $\text{SO}_2$  was used to prepare the solution which was then concentrated by pumping off  $\text{SO}_2$  to give an approximately 8–10% concentration of the carbonium ion solution.

**c. From Cycloalkanes.** The cycloalkane (1-methylcyclopentane, cyclohexane) and a tenfold (weight) excess of acid (1:1  $\text{FSO}_3\text{H}$ – $\text{SbF}_5$ ) were vigorously stirred at room temperature until they formed a homogeneous colorless mixture.

**d. From Cycloalkenes (1-Methylcyclopentene and Cyclohexene).** A cold ( $-60^\circ$ ) solution of the cycloalkene in  $\text{SO}_2$  was added slowly with stirring to a cold solution of  $\text{HF}$ – $\text{SbF}_5$  and  $\text{FSO}_3\text{H}$ – $\text{SbF}_5$  in  $\text{SO}_2$ . Excess  $\text{SO}_2$  was pumped off in order to obtain a  $\sim 10\%$  solution of the methylcyclopentyl cation.

Quenching the methylcyclopentyl cation in a suspension of methanol and potassium carbonate at  $-78^\circ$  gave an 81% yield of 1-methylcyclopentene according to comparison with authentic samples.

**Acknowledgment.** Support of this work by grants of the National Science Foundation and the Petroleum Research Fund administered by the American Chemical Society is gratefully acknowledged.

## Stable Carbonium Ions. XXXVIII.<sup>1</sup> Alkenyloxocarbonium Ions

George A. Olah and Melvin B. Comisarow<sup>2</sup>

Contribution from the Department of Chemistry, Case Western Reserve University, Cleveland, Ohio 44106. Received December 21, 1966

**Abstract:** An investigation of the alkenoyl fluoride–antimony pentafluoride complexes has been carried out. Acryloyl-, methacryloyl-, crotonoyl-, tigloyl-,  $\beta,\beta$ -dimethylacryloyl-, and cinnamoyl fluoride all form complexes with antimony pentafluoride, which based on infrared and nmr investigations are alkenyloxocarbonium ions.

No investigation of the complex formation of alkenoyl halides with Lewis acid halides has been reported in the literature. Deno, Pittman, and Wisotsky<sup>3</sup> investigated the behavior of crotonic, 2-methylcrotonic (tiglic), 3-methylcrotonic, and 2,4-hexadienoic (sorbic) acid in sulfuric acid and oleum. It was suggested, based on nmr studies, that an equilibrium exists between the oxocarbonium ions and protonated acids.

In continuation of our previous work<sup>4</sup> on oxocarbonium ions it was of interest to attempt the preparation of alkenyloxocarbonium ion complexes ( $\text{RC}^+=\text{O}$ , R = unsaturated).

## Results and Discussion

Stable alkenyloxocarbonium ion complexes were obtained by treating alkenoyl fluorides with antimony pentafluoride ("fluoride method" of oxocarbonium ion formation<sup>4</sup>).

The necessary alkenoyl fluorides were prepared from the corresponding acyl chlorides and anhydrous hydrogen fluoride except for acryloyl fluoride, methacryloyl fluoride, and crotonoyl fluoride, which were prepared from the corresponding acids and benzoyl fluoride. Yields were generally better than 90%. Table I summarizes the boiling points of the alkenoyl fluorides. Their purity, based on nmr and infrared spectra, was better than 98%.

The alkenyloxocarbonium ion complexes were prepared by mixing cold 1,1,2-trifluoroethane (Freon 113) solutions of the corresponding alkenoyl fluorides with Freon 113 solutions of antimony pentafluoride. The complexes separate as liquids at room temperature except for the cinnamoyl complex which crystallizes (mp  $75^\circ$ ). They are all brown in color except for the cinnamoyl complex which is bright red.

1.

stored in the absence of moisture the complexes are to be stable indefinitely.

## Alkenoyl Fluorides

Fluoride	Bp, °C (mm)
Acryloyl	34 <sup>a</sup>
Methacryloyl	56–57 <sup>b</sup>
Crotonoyl	80–82 <sup>a</sup>
Tigloyl	63–64 (180)
$\beta,\beta$ -Dimethylacryloyl	66 (188)
Cinnamoyl	108 (12) <sup>d</sup>

<sup>a</sup> 34.5°. <sup>b</sup> B. W. Howk and R. A. Jacobson [U. S. Patent 3,000,000; *Chem. Abstr.*, 42, 4794 (1948)] report 56.5–58°. <sup>c</sup> F. J. Langer [*Ber.*, 91, 2553 (1958)] report 81–82° (745 mm). <sup>d</sup> 108° (12 mm).

**Infrared Investigations.** The liquid complexes were prepared as neat films between Irtran-2 plates using the same techniques for exclusion of moisture.<sup>4d</sup> The solid cinnamoyl complex was examined as a Fluoromull.

Infrared investigations show that all of the complexes are exclusively oxocarboxonium ions ( $RC^+=O$ ) as indicated by the absence of carbonyl absorption in the presence of an absorption band (around 2240  $cm^{-1}$ ) characteristic of oxocarboxonium ions.<sup>4</sup> The infrared absorption data are summarized in Table II.

Methacryloyl	1815	1645	2240	1590
Crotonoyl	1815	1655	2240	1580
Tigloyl	1800	1650	2230	1580
$\beta,\beta$ -Dimethylacryloyl	1800	1645	2220	1555
Cinnamoyl	1805	1640	2210	1550

The  $C^+=O$  stretching frequency is generally close to 1600  $cm^{-1}$ , which is lower than the  $C^+=O$  stretching frequency found in saturated alkyloxocarboxonium ions<sup>4</sup> and close to the stretching frequency of the phenyloxocarboxonium ion (2212  $cm^{-1}$ ). This is undoubtedly due to conjugation with the adjacent double bond. As found previously for other oxocarboxonium ions<sup>4d</sup> the absence of carbonyl absorption bands is dependent on the purity of the complexes. Addition of water to the complexes diminishes the intensity of the 2240- $cm^{-1}$  band and causes a concomitant appearance of a band at 1600  $cm^{-1}$ . The spectrum of the acryloyl complex is shown in Figure 1 as representative of the infrared spectra of the alkenyloxocarboxonium ions.

Figure 2.

Figure 3.

**Nmr Investigations.** The pmr spectra of the alkenyloxocarboxonium hexafluoroantimonate complexes and the starting acyl fluorides as solution in  $SO_2$  at  $-40$  to  $-60^\circ$  are shown in Figures 2–7. First-order techniques were used for the analysis of all of the spectra except that of acryloyl fluoride.<sup>5</sup> The data are summarized in Table III. They clearly indicate the oxocarboxonium ion nature of the investigated complexes. The deshielding ( $\Delta\delta$  values) of the methyl protons  $\beta$  to the  $C^+=O$  group is greater than that of the  $\alpha$ -methyl protons, indicating substantial contributions from the resonance forms I and II. Comparison of  $\Delta\delta$  values

indicates that the proton *cis* to the  $C^+=O$  group in the cinnamoyl complex is deshielded less than the same proton in the other complexes indicating a further strong contribution from resonance form III.

<sup>a</sup> These values were obtained from ref 5b by adding 0.1 from the chemical shifts in  $\text{CFCl}_3$ ; +0.1 ppm is a typical solvent shift from  $\text{CFCl}_3$  (internal TMS) to  $\text{SO}_2$  (external TMS): Olah and Comisarow, unpublished data.

room temperature (with the exception of the cinnamoyl complex) and their spectra were very similar to the solution spectra except for the solvent shift. The resolution of the neat spectra was slightly lower due to the higher viscosity of the neat complexes as compared with their  $\text{SO}_2$  solutions.

The  $\text{F}^{19}$  spectra of the complexes shows no C-F resonances, only antimony-fluorine peaks at around  $\phi + 100$  (parts per million from external  $\text{CFCl}_3$ ).

### Experimental Section

Acryloyl, methacryloyl, and crotonoyl fluorides were prepared from the acids and benzoyl fluoride using the published procedure for cyclopropanecarbonyl fluoride.<sup>4d</sup> Tigloyl,  $\beta,\beta$ -dimethylacryloyl, and cinnamoyl fluorides were prepared from the corre-

sponding chlorides and anhydrous hydrogen fluoride using the published procedure for preparing cyclobutanecarbonyl fluoride.<sup>4d</sup>

The preparation of the alkenyloxocarbenium ion complexes from alkenoyl fluorides and antimony pentafluoride in 1,1,2-trifluoroethane solution was carried out according to methods previously described to prepare other types of oxocarbenium complexes.<sup>4a-d</sup>

The techniques of infrared and nmr studies were also analogous to those described previously. Infrared spectra were obtained on a Beckman Model IR 10 spectrophotometer and a PE 337 spectrophotometer. Nmr spectra were obtained on Varian Associates Model HA-60-IL and A56-60A spectrometers equipped with variable-temperature probes. All chemical shifts are relative to external TMS ( $\text{H}^1$ ) or  $\text{CCl}_3\text{F}$  ( $\text{F}^{19}$ ) as references (capillary tubes).

## Carbodiimide-Sulfoxide Reactions. VI.<sup>1</sup> Syntheses of 2'- and 3'-Ketouridines

A. F. Cook<sup>2</sup> and J. G. Moffatt

Contribution No. 46 from the Institute of Molecular Biology, Syntex Research, Palo Alto, California. Received January 23, 1967

**Abstract:** Oxidation of 2',5'-di-O-trityluridine by the dimethyl sulfoxide-dicyclohexylcarbodiimide method gave crystalline 2',5'-di-O-trityl-3'-ketouridine in good yield. Treatment with hydrogen chloride in chloroform then gave free 3'-ketouridine. In a similar way oxidation of 3',5'-di-O-trityluridine gave 3',5'-di-O-trityl-2'-ketouridine which was detritylated to free 2'-ketouridine. These oxidations could also be performed using dimethyl sulfoxide together with acetic anhydride or phosphorus pentoxide. The uridine ketones were very labile toward alkali, being cleaved to uracil. Borohydride reduction of the free or tritylated 2'-ketone led predominantly to the formation of products with the arabinose configuration while similar reduction of the 3'-ketones gave mixtures of the corresponding xylosides and ribosides in a ratio of 2:1. Attempts to alkylate the ditrityl 3'-ketone with Grignard reagents, methyllithium, or diazomethane have not as yet been successful. Nuclear magnetic resonance spectra data are presented for the various compounds.

An extremely mild, yet efficient, oxidation of alcohols through their reaction with dimethyl sulfoxide (DMSO) and dicyclohexylcarbodiimide (DCC) has been developed in this laboratory.<sup>3</sup> Since the oxidation proceeds at room temperature, and under essentially neutral conditions (e.g., using pyridinium trifluoroacetate as the proton source), it has found considerable application when dealing with sensitive compounds.<sup>4</sup> A particular merit lies in the oxidation of primary alcohols exclusively to the aldehyde stage,<sup>5</sup> and this property has permitted the oxidation of the 5'-hydroxyl group of protected nucleosides to give the corresponding nucleoside 5'-aldehydes.<sup>3a,5</sup>

Our earlier observations<sup>3b</sup> showed that the reaction of deoxynucleosides, such as thymidine, substituted at the 5' position by phosphate, acetyl, or *p*-nitrobenzoyl groups (1,  $\text{R} = \text{thymine}$ ,  $\text{R}' = \text{PO}_3\text{H}_2$ , Ac, *p*-nitrobenzoyl) with DMSO and DCC in the presence of an-

hydrous orthophosphoric acid led to the rapid and complete cleavage of the N-glycosidic bond with release of thymine. Such a degradation undoubtedly proceeds *via* oxidation to the 5'-substituted 3'-ketonucleoside 2 which then undergoes  $\beta$  elimination of the heterocyclic base. The elimination step was apparently extremely rapid and no sign of the intermediate ketones 2 could be detected chromatographically. Similar results have been encountered by others during attempted oxidation of the 3'-hydroxyl group of protected deoxynucleosides with manganese dioxide,<sup>6</sup> chromium trioxide in pyridine,<sup>7</sup> or platinum and oxygen under forcing conditions.<sup>8</sup>

Figure 1. Nuclear magnetic resonance spectrum of 2',5'-di-O-trityl-3'-ketouridine in deuteriochloroform at 100 Mc.

In this paper we describe the successful oxidation of some doubly blocked uridine derivatives and the isolation of free 2'- and 3'-ketouridines.

The starting materials in this work were the well-known 2',5'-di-O-trityluridine (3) and 3',5'-di-O-trityluridine (4) which were obtained in yields of 39 and 19% by reaction of uridine with excess triphenylmethyl chloride in pyridine at 100° essentially according to Yung and Fox<sup>9a</sup> and Žemlička.<sup>9b</sup> Much of the 2',5'-ditrityl compound could be directly isolated by crystallization and the 3',5'-ditrityl isomer was obtained by chromatography of the mother liquors on a silicic acid column. In addition to these two products a small amount (2%) of the previously undescribed 2',3',5'-tri-O-trityluridine (5) was obtained in crystalline form and its structure was confirmed by elemental analysis and nuclear magnetic resonance spectroscopy. The presence of the third trityl group on a sugar hydroxyl rather than on N<sub>1</sub> of the uracil ring was shown by the ultraviolet spectrum which was typically that of a uridine derivative [ $\lambda_{\max}$  261 m $\mu$  ( $\epsilon$  9990)]. In addition, the nmr spectrum of 5 showed an interesting, and previously undescribed, coupling ( $J$  = 2 cps) of the N<sub>1</sub> and C<sub>5</sub> protons of the uracil ring. This effect, which was readily confirmed by spin-decoupling studies, was also noted with 3 and 4 as well as with the tritylated ketonucleosides to be described below.

Treatment of 3 with DMSO and DCC in the presence of pyridinium trifluoroacetate at room temperature led

- (9) (a) N. C. Yung and J. J. Fox, *J. Am. Chem. Soc.*, **83**, 3060 (1961);  
 (b) J. Žemlička, *Collection Czech. Chem. Commun.*, **29**, 1734 (1964).

to the smooth formation of a new, less polar product together with a little unreacted 3, as demonstrated by thin layer chromatography. Direct crystallization from methanol gave a 46% yield of pure 2',5'-di-O-trityl-3'-ketouridine (6) and preparative thin layer chromatography of the mother liquors on 1-m glass plates coated with a 1.3-mm layer of silicic acid gave a further 20% yield of the pure product. The compound had an ultraviolet spectrum typical of uridine derivatives [ $\lambda_{\max}$  261 m $\mu$  ( $\epsilon$  9600)] and had an infrared spectrum similar to that of 3 except for the presence of an additional carbonyl band at 1775 cm<sup>-1</sup>. Under nonaqueous conditions the product exists in the keto form as shown by its elemental analysis and its nmr spectrum. The latter is particularly revealing since the keto group effectively insulates the proton on C<sub>2'</sub> and C<sub>4'</sub> and thus leads to a spectrum in which the protons are clearly resolved and readily analyzed. The 100-Mc spectrum of 6 is shown as Figure 1 and all assignments have been confirmed by spin-decoupling studies. Figure 1 clearly shows the previously mentioned coupling of C<sub>5</sub>H and N<sub>1</sub>H of the uracil ring, these protons occurring as a doublet of doublets ( $J_{1,2}$  = 8 cps;  $J_{5,2}$  = 2 cps) at  $\delta$  5.11 and a doublet ( $J$  = 2 cps) at  $\delta$  8.63, respectively. Irradiation at  $\delta$  8.63 results in the collapse of the C<sub>5</sub> proton to a doublet ( $J_{1,2}$  = 8 cps) and irradiation at  $\delta$  5.11 reduces N<sub>1</sub>H to a singlet. The nonequivalence of the methylene protons is also striking, these protons appearing as a pair of quartets centered at  $\delta$  3.24 ( $J_{1',2'}$  = 10 cps,  $J_{4',5'a}$  = 2.2 cps) and  $\delta$  3.51 ( $J_{1',2'}$  = 10 cps,  $J_{4',5'b}$  = 5.2 cps). The C<sub>4'</sub>H occurs as a quartet at  $\delta$  4.30 and irradiation at this point reduces the methylene protons to a pair of geminally coupled ( $J$  = 10 cps) doublets. Similarly, irradiation at  $\delta$  4.30 collapses C<sub>4'</sub>H to a singlet at  $\delta$  4.30. The C<sub>1'</sub> and C<sub>2'</sub> protons occur as simple doublets at  $\delta$  5.69 and ( $J_{1',2'}$  = 6 cps) and irradiation of either collapses the other to a singlet. Addition of D<sub>2</sub>O to the sample ca

(11) Carbonyl absorptions in the 1770-cm<sup>-1</sup> region are known for other ketofuranosides. See, e.g., K. Onodera, S. Hirano, and K. Kashimura, *J. Am. Chem. Soc.*, **87**, 465 (1965).

of the  $N_3H$  for deuterium and eliminated the  $^{13}C_5H$  which then became a doublet.

We also examined the oxidation of **3** by the related DMSO-phosphorus pentoxide<sup>11</sup> and acetic anhydride<sup>12</sup> methods and found them to be unsuitable. These methods offer the distinct possibility of giving only water-soluble by-products, eliminating the necessity of removing dicyclohexylamine.

Using the phosphorus pentoxide method the starting alcohol **3** essentially disappeared and the yield of the ketone **6** could be obtained by crystallization. A further 15% yield could be obtained by preparative thin layer chromatography of the fractions and the remaining material appeared largely degraded to uracil which was identified in the aqueous extracts. A similar situation obtained in the DMSO-acetic anhydride reaction which gave a reaction mixture from which a 45% yield of ketone **6** could be obtained by crystallization.

We were unable to isolate either a 2,4-dinitrophenylhydrazone or a tosylhydrazone derivative of **6** and the oxime **7** could be obtained readily in 65% yield. Repeated attempts to reduce this oxime to a 3'-deoxynucleoside with hydrogen and palladium, as yet, been unsuccessful and treatment with aluminum hydride led to extensive degradation of the molecule. Treatment of **7** with 2 equivalents of hydrogen chloride in chloroform at 0° successfully removed the trityl groups giving the free 3'-ketouridine (**8**) which gave the expected nmr spectrum. It appeared to be unstable, becoming discolored on exposure to air and decomposing upon attempted crystallization. Palladium-catalyzed hydrogenation of **8** gave only unchanged starting material.

Reaction of the ditrityl ketone **6** with 2 equivalents of hydrogen chloride in chloroform at 0° gave smooth detritylation and precipitation of 3'-ketouridine (**9**) in quantitative yield. Elemental analysis of this material showed it to be the free ketone rather than the hydrate. On paper chromatography in borate buffer at pH 6.0,<sup>14</sup> however, it had a mobility of 1.2 times that of uridine and was roughly comparable to that of lyxofuranosyl uracil. This suggests hydration of the ketone in aqueous solution leading to a product that can form both 3',5'-borate complexes. Paper chromatography on bisulfite impregnated paper markedly increased the mobility of the ketone relative to uridine, being comparable to that of uridine 5'-aldehyde.

The ditrityl ketone **6** and the free ketone **9**, as glycosylamines, are extremely sensitive to alkaline conditions and readily undergo  $\beta$  elimination of the uracil moiety. Free 3'-ketouridine is especially sensitive and is instantaneously cleaved to uracil in borate buffer at room temperature during attempted crystallization. The free ketone had  $\lambda_{max}$  286 m $\mu$  typical of uracil derivatives, showed a broad maximum at 337 m $\mu$ .

Albright and L. Goldman, *J. Am. Chem. Soc.*, **87**, 4215 (1965).

This problem can also be circumvented by using diethylcarbamate in DMSO, the resulting diethylurea being water soluble: J. G. Moffatt, unpublished observations. See also: J. G. Moffatt, R. Fecher, and J. J. Fox, *J. Am. Chem. Soc.*, **82**, 560 (1960).

which is not present in uracil. The latter peak is presumably due to an unsaturated sugar fragment such as **10**, resulting from the elimination reaction. Attempts to prepare a quinoxaline derivative of **10** by addition of *o*-phenylenediamine failed, but uracil was identified in the alkaline mixture by paper chromatography. Rapid elimination of uracil also seemed to occur at pH 9.8, but was more difficult to follow since uracil and uridine have rather similar spectra below pH 10.5. The ditrityl 3'-ketone **6** was much more stable toward alkali than was **9** and the rate of release of uracil could be readily followed in 0.1 *N* methanolic sodium hydroxide by the increase in ultraviolet absorption at 285 m $\mu$  relative to that at 260 m $\mu$ . In this case only a very weak absorption at 330 m $\mu$  resulted and by plotting the ratio of optical densities at 285 and 260 m $\mu$  a half-time of 7 min was determined for **6** under these conditions. This increased stability due to the presence of the 2'- and 5'-trityl groups is perhaps a consequence of steric distortion of the furanose ring into a conformation less amenable to  $\beta$  elimination. It may be noted that attempted oxidation of 5'-O-tritylthymine (**1**, R = thymine, R' = trityl) with either DMSO-DCC in the presence of pyridinium trifluoroacetate or with DMSO-acetic anhydride led only to thymine and to considerable amounts of triphenylcarbinol without detectable accumulation of the intermediate ketone (**2**, R = thymine, R' = trityl). The presence of bulky substituents at both C<sub>2</sub>' and C<sub>5</sub>' thus appears to be a prerequisite for successful oxidation.

Reduction of the ditrityl ketone **6** with sodium borohydride in ethanol was rapid and separation of the products by preparative thin layer chromatography and crystallization gave a 59% yield of 1-(2,5-di-O-trityl-beta-D-xylofuranosyl)uracil (**11**) and 31% of 2',5'-di-O-trityluridine (**3**) in crystalline form. Both products had physical constants identical to those described by Yung and Fox.<sup>15</sup> Detritylation of the crude reduction mixture by treatment with hot 80% acetic acid gave a mixture of uridine and 1-(beta-D-xylofuranosyl)uracil (**12**) which were cleanly separated by borate

electrophoresis.<sup>14</sup> Quantitative estimation of the eluted spots by ultraviolet absorption showed that borohydride reduction of **6** gave 66% of the xylosyl derivative (**11**) and 34% of the ribose epimer **3**. This result indicates that the trityl ether at C<sub>2'</sub> offers less steric hindrance to approach by the reducing agent than does the uracil ring and the 5'-trityl group on the  $\beta$  face of the ribose ring. Borohydride reduction of free 3'-ketouridine (**9**) in aqueous ethanol was also studied and quantitative estimation of the two products by borate electrophoresis showed 1-( $\beta$ -D-xylofuranosyl)uracil (**12**) and uridine to be present in 69 and 31% yields, respectively. The similarity of these results to those with the ditrityl ketone once again emphasizes the predominant directive influence of the uracil ring in the reduction process.

The oxidation of 3',5'-di-O-trityluridine (**4**) has also been accomplished. Thus treatment with DMSO-DCC in the presence of pyridinium trifluoroacetate gave some unreacted **4** together with the major product, 3',5'-di-O-trityl-2'-ketouridine (**13**), which was isolated in pure form in 63% yield by preparative thin layer chromatography. In spite of repeated efforts we have been unable to obtain this product in crystalline form. Its structure, however, is certain from its elemental analysis and nmr spectrum, the latter clearly showing the C<sub>1'</sub> proton as a sharp singlet at  $\delta$  5.79, and the C<sub>3</sub>-H as a doublet ( $J_{3,4'} = 4$  cps) at  $\delta$  4.40. Coupling between C<sub>5</sub>H and N<sub>3</sub>H ( $J_{5,6} = 2$  cps) was again apparent but, unlike **6**, the 5'-methylene protons were equivalent and appeared as a doublet ( $J_{5,4'} = 4$  cps) at  $\delta$  2.91.

Oxidation of **4** with DMSO-phosphorus pentoxide at 65° was also successful and gave a 52% yield of only slightly impure **13** by precipitation from the crude, extracted reaction mixture without chromatography. Once again an appreciable amount of uracil was found in the aqueous extracts. In a similar way oxidation of **4** by DMSO-acetic anhydride gave a 56% yield of slightly impure **13** by precipitation without chromatography.

Treatment of the ditrityl ketone **13** with 2 equiv of anhydrous hydrogen chloride in chloroform at 0° led to the precipitation of chromatographically and analytically pure 2'-ketouridine (**14**) in 72% yield. The nmr spectrum of **14** was completely compatible with the assigned structure, the C<sub>1</sub>-H once again appearing as a sharp singlet at  $\delta$  5.42, and the C<sub>3</sub>-H as a doublet ( $J = 9$  cps) at  $\delta$  7.30, both confirming the absence of a proton at C<sub>2</sub>. For convenience a tabulation of 100-Mc nmr assignments for a number of the uridine nucleosides described in this paper is given in Table I and all have been confirmed by spin-decoupling studies. A crystalline 2,4-dinitrophenylhydrazone of 2'-ketouridine was readily prepared using the extremely useful method of Parrick and Rasburn<sup>15</sup> with DMSO as solvent. The reduction of both the ditrityl 2'-ketone **13** and the free 2'-ketone **14** has been examined using sodium borohydride in ethanol and gave results quite similar

to those with the 3'-keto compounds. Thus reduction of **13** gave predominantly 1-(3,5-di-O-trityl- $\beta$ -D-arabinofuranosyl)uracil<sup>16</sup> (**15**) and lesser amounts of 3',5'-di-O-trityluridine (**4**) which were isolated in yields of 57 and 11% by preparative thin layer chromatography. Removal of the trityl groups from these compounds gave 1-( $\beta$ -D-arabinofuranosyl)uracil (**16**) and uridine, which were identified by comparison with authentic samples using borate electrophoresis and paper chromatography. Direct acid hydrolysis of the borohydride reduction mixture followed by borate electrophoresis showed that the products were the arabinosyl and the ribosyl derivatives in yields of 82 and 18%, respectively. In a similar way, reduction of free 2'-ketouridine (**14**) followed by quantitative borate electrophoresis showed the products to be arabinosyluracil (**16**) and uridine in yields of 90 and 10%. The predominant directive influence of the uracil ring on the reduction process is once again evident, the greater stereoselectivity being a consequence of the closer proximity of the heterocyclic base and the keto group. The reduction of 2'- and 3'-ketouridines with tritiated sodium borohydride provides a convenient synthesis of the specifically 2'-tritiated arabinosyluracil and uridine and 3'-tritiated xylosyluracil and uridine, and these results will be reported elsewhere.<sup>17</sup>

The action of alkali on the 2'-ketouridines has also been studied and, as with 3'-ketouridine, it was shown that essentially instantaneous elimination of uracil took place in either 0.01 *N* sodium hydroxide or in pH 10.8 buffer. Thus while **14** had the typical ultraviolet spectrum of uridine under neutral conditions the spectrum of a freshly prepared solution at pH 10.8 showed a maximum at 286 m $\mu$  typical of uracil and a second maximum at 337 m $\mu$  similar to that found with 3'-ketouridine. Uracil could be identified by paper chromatography and the other elimination product has not been studied further. A similar alkaline instability of the ditrityl 2'-ketone **13** was also observed and uracil could be readily identified by thin layer and

<sup>a</sup> Spectra in deuteriochloroform unless otherwise noted. <sup>b</sup> (s) = singlet, (d) = doublet, (t) = triplet, (q) = quartet (m) = multiplet. <sup>c</sup> Deuteriodimethyl sulfoxide. No hydroxyl coupling was evident. <sup>d</sup> In trityl envelope. <sup>e</sup> Some further undefined coupling ( $J = 0.5$  also present).

chromatography. Determination of the rate of elimination by examination of ultraviolet spectral changes was, however, rendered impossible by the formation of an orange color and broad absorption below 270 mμ. When the alkaline treatment was on a larger scale the appearance of the orange color was accompanied by the separation of a cream-colored solid. From this material it was possible to isolate a crystalline compound identified as bis(triphenylmethyl)uracil<sup>18</sup> by physical constants, elemental analyses, and spectral data. The mechanism by which this uracil is formed remains obscure but its formation was markedly reduced by conducting the alkaline treatment under nitrogen. In addition to uracil, 2'-enylcarbinol was the only other major product

identified in the methanol-soluble fractions from the alkaline reaction mixture.

A number of attempts have been made to alkylate the carbonyl group of 2',5'-di-O-trityl-3'-ketouridine so as to prepare branched chain nucleosides such as 3'-C-methyluridine (17).<sup>19</sup> In general, however, reactions of 6 with methyl Grignard reagents in ether, tetrahydrofuran, monoglyme, or tetrahydrothiophene<sup>20</sup> under a variety of conditions led to no observable products. In most cases some precipitation resulted upon addition of the Grignard reagent but the lack of

(19) The analogous 2'-C-methyladenosine and 3'-C-methyladenosine have been recently described by other routes. See E. Walton, S. R. Jenkins, R. F. Nutt, M. Zimmerman, and F. W. Holly, *J. Am. Chem. Soc.*, **88**, 4524 (1966), and E. Walton, F. W. Holly, and R. F. Nutt, Abstract 37C of the Winter Meeting of the American Chemical Society, Phoenix, Ariz., Jan 1966.

Figure 2. Optical rotatory dispersion spectra of 2',5'-di-O-trityl-3'-ketouridine (6) —, and of 3',5'-di-O-trityl-2'-ketouridine (13) ---, in methanol.

any alkylation was confirmed by thin layer chromatographic identification of unreacted starting material and by borohydride reduction to the previously described xyloside 11 and riboside 3. As yet no successful methylation has been achieved using methylolithium in ether, tetrahydrofuran, or monoglyme. Under these conditions extensive decomposition of the ketone, and of 2',5'-ditrityluridine itself, was apparent.

An attempt was also made to react 6 and 13 with diazomethane, a reaction that has been successfully applied to alkylation of protected keto sugars.<sup>21</sup> Methylation at N<sub>3</sub> of the uracil ring was, of course, an expected side reaction.<sup>22</sup> After storage of 6 with an excess of diazomethane in ether thin layer chromatography indicated the presence of one major product and several minor ones. The major product was isolated, treated with sodium borohydride, and then detritylated with acetic acid giving two products. These were identified by both paper chromatography and borate electrophoresis as N<sub>3</sub>-methyl-1-(β-D-xylofuranosyl)uracil (18) and N<sub>3</sub>-methyluridine (19), authentic samples of which were prepared by the action of diazomethane on 2',5'-di-O-trityl-1-(β-D-xylofuranosyl)uracil (11) and 2',5'-di-O-trityluridine (3), respectively, followed by acid hydrolysis. Thus while N-methylation readily occurred, alkylation of the keto group cannot have taken place to more than a minor degree.

Further work will, however, be necessary in order to fully explore the possibility of using 2'- and 3'-keto-nucleosides as synthetic intermediates.

A final point of interest concerns a comparison of the optical rotatory dispersion (ORD) spectra of the 2'- and 3'-ketouridine derivatives 6 and 13 which are shown in Figure 2. It can be seen from Figure 2 that the 2'-ketone (13) has a positive Cotton effect (molecular amplitude 191) with a zero rotation at 265 mμ similar to that of uridine<sup>23</sup> or 2',5'-ditrityluridine. The 3'-ketone 6, however, shows a positive Cotton effect (amplitude 307) displaced toward longer wavelengths and showing zero rotation at 310 mμ. A second maximum is also present at lower wavelengths and is more pronounced when dioxane is used as the solvent. The position of this Cotton effect indicates its relationship to the n-π\* transition of the carbonyl group rather than to the uracil ring. A similar effect is noted in the optical rotatory dispersion curves of the detritylated 2'- and 3'-ketouridines (14 and 9) which showed zero rotations at 265 and 302 mμ, respectively.

Further work on the synthesis of other ketonucleosides is in progress and will be reported at a later date.

## Experimental Section

**Methods.** Thin layer chromatography was carried out on 0.25-mm layers of Merck silica gel GF, and the products were visualized by ultraviolet absorption or by spraying with a 5% solution of ammonium molybdate in 10% sulfuric acid followed by brief heating at 150°. Preparative thin layer chromatography was done on 20 × 100 cm glass plates coated with a 1.3-mm layer of Merck silica gel HF and column chromatography on Merck silica with 0.05–0.20-mm particles. Nuclear magnetic resonance spectra were obtained using solutions in deuteriochloroform (unless otherwise stated) and either a Varian A-60 or HA-100 spectrometer. Mass spectra were determined using an Atlas CH-4 spectrometer with a direct inlet system. Ultraviolet spectra were determined using a Cary Model 15 instrument and infrared spectra were obtained from potassium bromide pellets on a Perkin-Elmer Model 237 instrument. Optical rotatory dispersion spectra were obtained using a Jasco Model ORD/UV-5 instrument. Instrumental analyses were performed by the staff of the Analytical Laboratory of Syntex Research. We are particularly grateful to Mr. J. Murphy and to Drs. T. Toube and L. Tokes for their painstaking assistance with nmr and mass spectrometry respectively. Elemental analyses were obtained from Dr. A. Bernhardt, Mulheim, Germany.

**Tritylation of Uridine.** Uridine (15 g, 61.5 mmoles) and triphenylmethyl chloride (51.4 g, 183 mmoles) were stored overnight in pyridine (150 ml) and then heated at 100° for 4 hr. The light brown solution was poured into vigorously stirred ice water, and the gummy precipitate was dissolved in chloroform, washed with cadmium chloride solution and then with water, dried over sodium sulfate, and evaporated to a yellow syrup. Crystallization from benzene-ether gave 13.6 g (30%) of 2',5'-di-O-trityluridine (3) which was homogeneous by thin layer chromatography using chloroform-ethyl acetate (1:1) and had mp 217–220° (lit. mp 224–225°<sup>24</sup> and 215–220°<sup>25</sup>); λ<sub>max</sub><sup>dioxane</sup> 261 mμ (ε 9100). The nmr spectrum in deuteriochloroform is recorded in Table I.

Chromatography of the combined mother liquors<sup>24</sup> on 1200 g of silicic acid using chloroform-ethyl acetate (1:1) gave a small amount (2%) of 2',3',5'-tri-O-trityluridine (5) of mp 286–288° from ethyl acetate after final purification by preparative thin layer chromatography using chloroform-ethyl acetate (10:1); λ<sub>max</sub><sup>dioxane</sup> 261 mμ (ε 9990); [α]<sub>D</sub><sup>25</sup> -37.5° (c 0.1, chloroform). The nmr spectrum is recorded in Table I.

**Anal.** Calcd for C<sub>36</sub>H<sub>34</sub>N<sub>2</sub>O<sub>8</sub>: C, 81.65; H, 5.57; N, 2.89; O, 9.90. Found: C, 81.53; H, 5.74; N, 3.06; O, 10.15.

(23) T. L. V. Ulbricht, J. P. Jennings, M. M. Scopes, and W. Klyne, *Tetrahedron Letters*, 695 (1964).

(24) The trityluridine was actually found almost exclusively in the mother liquors from recrystallization of the second and third crops of 2',5'-ditrityluridine.

tylation with 80% acetic acid at 100° for 1 hr gave crystalline

Continued elution gave a further 3.8 g of crystalline trityluridine (total yield 39%) followed by 8.4 g (19%) of topographically homogeneous but apparently amorphous *O*-trityluridine (4) with  $\lambda_{\text{max}}^{\text{dioxane}}$  261 m $\mu$  ( $\epsilon$  9540) and  $[\alpha]_D^{25}$  (c 0.1, chloroform). See Table I for the nmr spectral

**Di-*O*-trityl-3'-ketouridine (6).** (a) By the DMSO-DCC. 2',5'-Di-*O*-trityluridine (3.02 g, 4 mmoles) was dissolved in mixture of anhydrous DMSO<sup>28</sup> (15 ml) and benzene (15 ml) in dicyclohexylcarbodiimide (2.48 g, 12 mmoles) and pyridine (32 ml, 4 mmoles). Trifluoroacetic acid (0.16 ml, 2 mmoles) was added, and the mixture was stored overnight at room temperature. Oxalic acid (1.3 g, 12 mmoles) was then added to destroy DCC and after 30 min, chloroform (50 ml) and water (50 ml) were added and dicyclohexylurea was removed by filtration. The chloroform layer was rapidly extracted twice with 1 *N* sodium hydroxide and then with water. It was then dried over sodium sulfate and evaporated leaving a residual froth which was dissolved in methanol, seeded,<sup>29</sup> and allowed to slowly cool giving 1.40 g of 2',5'-di-*O*-trityl-3'-ketouridine (6) of mp 146–148° undepressed upon recrystallization,  $\lambda_{\text{max}}^{\text{MeOH}}$  261 m $\mu$  ( $\epsilon$  9600);  $[\alpha]_D^{25}$  (c 0.1, chloroform). The nmr and optical rotatory dispersion spectra are shown as Figures 1 and 2 and are discussed in

Calcld for  $\text{C}_{27}\text{H}_{30}\text{N}_4\text{O}_6$ : C, 77.67; H, 5.27; N, 3.85. Found: C, 77.54; H, 5.17; N, 4.02; O, 13.01.

The mother liquors were evaporated leaving 1.8 g of a syrup that was chromatographed on four 20  $\times$  100 cm preparative thin layer plates using chloroform-ethyl acetate (10:1) which separated the 2',5'-ditrityluridine from the faster moving ketone. The ketone band was eluted with acetone giving 890 mg of the homomeric ketone which was crystallized from methanol giving 620 mg of pure material, 2.02 g, 66% yield.

**Using DMSO-Phosphorus Pentoxide.**<sup>11</sup> Phosphorus pentoxide (1.74 g, 12 mmoles) was added slowly to anhydrous dimethyl sulfoxide (75 ml). After the mixture cooled 2',5'-di-*O*-trityluridine (3.02 g, 4 mmoles) was added, and the mixture was stirred at 60° for 2 hr. Ether (200 ml) was added, and the solution was extracted three times with 5% aqueous sodium bicarbonate and then with water.

After drying with sodium sulfate and evaporating the solvent, 6.33 g of a solid froth remained and was directly crystallized from methanol with slow cooling giving 3.08 g (42%) of the ketone 6 in two crops. The mother liquors were then chromatographed on 200 g of silicic acid using chloroform-ethyl acetate (10:1) giving a further 1.08 g of pure product (total yield 57%) upon recrystallization from methanol. The product was identical to that from the DMSO-DCC reaction.

**Using DMSO-Acetic Anhydride.**<sup>12</sup> 2',5'-Ditrityluridine (3.02 g, 4 mmoles) was dissolved in DMSO (65 ml) and acetic anhydride (20 ml) and stored overnight at room temperature. The acetic anhydride was then evaporated *in vacuo* leaving a residue which was dissolved in ether, extracted three times with 5% aqueous sodium bicarbonate, then with water, and dried over sodium sulfate.

After evaporation of the solvent the residue was crystallized from methanol giving 3.18 g (44%) of the pure ketone 6, mp 146–148°.

**2',5'-Di-*O*-trityl-3'-oximinouridine (7).** 2',5'-Di-*O*-trityl-3'-ketouridine (6, 1.01 g) was dissolved in pyridine (20 ml) together with hydroxylamine hydrochloride (1.02 g), and the mixture was stirred at 60° for 2.5 hr at which time thin layer chromatography using chloroform-ethyl acetate (6:1) showed the disappearance of the ketone material and formation of a somewhat slower product. The solvent was then evaporated to dryness, and the residue was extracted with chloroform. After extraction with aqueous cadmium acetate and then water, the solution was dried with sodium sulfate and evaporated leaving 1.32 g of a white froth which was crystallized from ethanol giving 0.67 g (65%) of the pure oxime 7, mp 70–72°;  $\lambda_{\text{max}}^{\text{dioxane}}$  260 m $\mu$  ( $\epsilon$  9900);  $[\alpha]_D^{25}$  +38.2° (c 0.1, chloroform).

Calcld for  $\text{C}_{27}\text{H}_{30}\text{N}_4\text{O}_6$ : C, 76.11; H, 5.26; N, 5.67. Found: C, 75.94; H, 5.26; N, 5.80.

ORD spectrum in dioxane showed a positive Cotton effect with a maximum at 282 m $\mu$  (molecular rotation +27,000°), zero rotation at 260 m $\mu$ , and a shoulder at 245 m $\mu$  (molecular rotation +12,000°).

Distilled and stored over Linde Molecular Sieve Type 4A. Initial seeds were obtained by crystallization of material from the reaction that was purified by preparative thin layer chromatography using chloroform-ethyl acetate (8:1).

–23,500°). The nmr spectrum in DMSO-*d*<sub>6</sub> showed the oximino hydrogen as a singlet at  $\delta$  11.77.

Attempted reduction of 7 with hydrogen and palladium on barium sulfate<sup>27</sup> in ethyl acetate was unsuccessful and using lithium aluminum hydride in tetrahydrofuran there was extensive loss of ultraviolet-absorbing materials.

**3'-Ketouridine (9).** 2',5'-Ditrityl-3'-ketouridine (1.228 g, 1.69 mmoles) was dissolved in dry chloroform (20 ml) and cooled to 0°. A freshly standardized solution of hydrogen chloride in chloroform (9.3 ml of 0.40 *N*, 3.72 mmoles) was then added dropwise with stirring over 20 min, and the mixture was stirred for 1 hr more. The resulting white precipitate was then collected by centrifugation, washed six times with 25-ml portions of ether, and dried *in vacuo* over potassium hydroxide giving 404 mg (99%) of 3'-ketouridine as an amorphous white solid that was not obtained crystalline but melted at 130–138°.

Anal. Calcd for  $\text{C}_9\text{H}_{10}\text{N}_2\text{O}_6$ : C, 44.63; H, 4.16; N, 11.57. Found: C, 44.76; H, 4.32; N, 11.51.

The product was homogeneous by thin layer chromatography with chloroform-methanol (4:1) having an *R<sub>f</sub>* identical with that of uracil, and on paper using *n*-butyl alcohol-acetic acid-water (5:2:3) where it had *R<sub>f</sub>* 0.41, just faster than uridine. Using the same solvent system with paper previously impregnated with sodium bisulfite it had a very low *R<sub>f</sub>* while uracil moved normally. On paper electrophoresis<sup>14</sup> in 1 *M* boric acid adjusted to pH 6.0 using 1000 v for 4 hr 9 had a mobility of 1.2 relative to uridine while uracil remained on the origin;  $\lambda_{\text{max}}^{\text{H}_2\text{O}}$  261 m $\mu$  ( $\epsilon$  9400);  $[\alpha]_D^{25}$  +71.2° (c 0.1, water).

The ORD spectrum in water showed a positive Cotton effect with a maximum at 316 m $\mu$  (molecular rotation +4400°), zero rotation at 292 m $\mu$ , and a minimum at 251 m $\mu$  (molecular rotation –8420°).

**Borohydride Reduction of 6 and 9.** (a) 2',5'-Di-*O*-trityl-3'-ketouridine was dissolved in ethanol (15 ml) and sodium borohydride (286 mg) was added. After 1 hr at room temperature the solution was partitioned between chloroform and water, and the chloroform solution was washed three times with water, dried over sodium sulfate, and evaporated to dryness. Crystallization from benzene-ether gave a first crop (55 mg) of pure 2',5'-di-*O*-trityluridine, mp 219–221°, undepressed on admixture with an authentic sample. The infrared spectra were also identical. The mother liquors were then chromatographed on three 20  $\times$  100 cm preparative thin layer plates using carbon tetrachloride-acetone (4:1) which clearly resolved two bands. Elution of the faster band with acetone gave a further 35 mg of 2',5'-ditrityluridine after crystallization from ether (total yield 31%). The slower band gave, after elution with acetone, 210 mg of a crystalline residue which was recrystallized from ethanol giving 170 mg of pure 1-(2,5-di-*O*-trityl- $\beta$ -D-xylofuranosyl)uracil, mp 150–154° (lit.<sup>26</sup> mp 151.5–153.5°). The nmr spectrum indicated the presence of 1 mole of ethanol of crystallization rather than one-half mole as described previously;<sup>26</sup>  $\lambda_{\text{max}}^{\text{dioxane}}$  258 m $\mu$  ( $\epsilon$  11,760);  $[\alpha]_D^{25}$  +49.6° (c 0.1, chloroform). The ORD spectrum in methanol showed a positive Cotton effect with a maximum at 276 m $\mu$  (molecular rotation +20,100°), zero rotation at 272 m $\mu$ , and a minimum at 242 m $\mu$  (molecular rotation –20,100°).

A small portion (11 mg) of the crude reduction mixture was also treated with 80% acetic acid (1 ml) at 100° for 1 hr, evaporated to dryness, and examined by electrophoresis in pH 6.0 borate buffer at 1000 v for 4 hr. Elution of the two resulting spots which had mobilities of 1.0 and 0.67 relative to uridine showed the reduction to give 34% uridine and 66% 1- $\beta$ -D-xylofuranosyluracil (12).<sup>28</sup>

(b) 3'-Ketouridine (7.2 mg) was dissolved in water (1 ml) together with sodium borohydride (8 mg). After 30 min the solution was neutralized with Dowex 50 (H<sup>+</sup>) resin and directly examined by borate electrophoresis. Quantitative elution of the resulting spots with 0.1 *N* hydrochloric acid showed the products to be 31% uridine and 69% xylosyluracil.

**Action of Alkali on 6 and 9.** (a) 2',5'-Di-*O*-trityl-3'-ketouridine was dissolved in methanol at a concentration of 106.3  $\mu$ g/ml and diluted with an equal volume of 0.2 *N* methanolic sodium hydroxide. The ultraviolet spectrum of the solution was recorded at intervals over 2 hr, and the course of the reaction was followed by the ratio of absorbance at 285 and 260 m $\mu$ . The initial 285:260 ratio was 0.17 and the final value was 1.40. The half-time of the reaction was 7 min, and the product was identified as uracil by paper and thin layer chromatography.

(28) We are grateful to Dr. J. J. Fox for an authentic sample of 12.

(b) An aqueous solution of 3'-ketouridine in water at a concentration of 20.20  $\mu\text{g}/\text{ml}$  ( $\lambda_{\text{max}}$  262  $\text{m}\mu$ ) was diluted with an equal volume of 0.05 *M* carbonate buffer (pH 10.8). Within 2 min the spectrum showed the complete disappearance of the 262- $\text{m}\mu$  peak with formation of two new maxima at 286 and 336  $\text{m}\mu$  of roughly equal intensities. Paper chromatographic examination of a more concentrated solution showed a strong spot identical with uracil.

**3',5'-Di-O-trityl-2'-ketouridine (13).** (a) Using DMSO-DCC. 3',5'-Di-O-trityluridine (728 mg, 1 mmole) was dissolved in a mixture of DMSO (10 ml) and benzene (10 ml) containing DCC (0.62 g, 3 mmoles) and pyridine (0.075 ml, 1 mmole). Trifluoroacetic acid (0.04 ml, 0.5 mmole) was added and after 16 hr at room temperature oxalic acid (0.38 g, 3 mmoles) was added. After 30 min the mixture was diluted with chloroform (50 ml), filtered, and extracted with aqueous sodium bicarbonate, followed by water. The chloroform solution was dried over sodium sulfate and evaporated *in vacuo* leaving 1.02 g of a white froth that was separated by preparative thin layer chromatography on three 20  $\times$  100 cm plates using two consecutive developments with chloroform-ethyl acetate (9:1). The slower band was eluted with acetone giving 217 mg (30%) of unreacted 3',5'-ditrityluridine while the faster band gave 455 mg (63%) of chromatographically homogeneous 3',5'-di-O-trityl-2'-ketouridine which we have been unable to crystallize but which melted at 130–135°;  $\lambda_{\text{max}}^{\text{MeOH}}$  260  $\text{m}\mu$  ( $\epsilon$  10,900);  $[\alpha]_D^{25} + 30.8^\circ$  (*c* 0.1, chloroform).

*Anal.* Calcd for  $\text{C}_{27}\text{H}_{24}\text{N}_4\text{O}_6$ : C, 77.67; H, 5.27; N, 3.85. Found: C, 77.77; H, 5.50; N, 3.91.

The ORD spectrum is shown in Figure 2, and significant features of the nmr spectrum are discussed in the text. The carbonyl group appeared in the infrared spectrum at 1785  $\text{cm}^{-1}$  (KBr) and at 1790  $\text{cm}^{-1}$  ( $\text{CCl}_4$ ).

(b) Using DMSO-Phosphorus Pentoxide. 3',5'-Di-O-trityluridine (3.85 g, 5.3 mmoles) was added to a solution of phosphorus pentoxide (0.90 g, 6.3 mmoles as  $\text{P}_2\text{O}_5$ ) in DMSO (25 ml), and the solution was heated for 1 hr at 65°. It was then diluted with ether, washed with aqueous sodium bicarbonate, dried, and evaporated leaving an off-white froth (2.77 g) which contained several minor by-products in addition to 13. This was dissolved in ether and precipitated with hexane giving 1.99 g (52%) of 13 of sufficient purity for most purposes. Completely pure product could be obtained by preparative thin layer chromatography.

(c) Using DMSO-Acetic Anhydride. 3',5'-Di-O-trityluridine (1.46 g, 2 mmoles) was treated overnight at room temperature with a mixture of DMSO (10 ml) and acetic anhydride (4 ml). The acetic anhydride was largely evaporated *in vacuo*, and the residue was dissolved in ether and extracted twice with aqueous sodium bicarbonate and then with water. Evaporation of the solvent left 1.39 g of a froth which was dissolved in ether and precipitated with hexane giving 858 mg (56%) of 13 containing only minor impurities. Detritylation of the nonprecipitated fraction gave a complex mixture of products that was not studied further.

**2'-Ketouridine (14).** 3',5'-Di-O-trityl-2'-ketouridine (597 mg, 0.82 mmole) was dissolved in dry chloroform (20 ml) and cooled to 0°. A solution of hydrogen chloride in chloroform (8 ml of 0.23 *N*, 1.84 mmoles) was added dropwise over 15 min and stirring was continued for a further 30 min. The precipitated solid was collected by centrifugation and washed six times with 25-ml portions of ether. The white residue was then dried *in vacuo* over potassium hydroxide giving 144 mg (72%) of 2'-ketouridine (mp 186–189°) which ran as a single spot just ahead of uridine on borate electrophoresis and as a somewhat elongated spot between uridine and uracil on thin layer chromatography using chloroform-methanol (4:1);  $\lambda_{\text{max}}^{\text{H}_2\text{O}}$  261  $\text{m}\mu$  ( $\epsilon$  9600);  $[\alpha]_D^{25} + 43.7^\circ$  (*c* 0.1, water).

*Anal.* Calcd for  $\text{C}_8\text{H}_{10}\text{N}_2\text{O}_5$ : C, 44.63; H, 4.16; N, 11.57. Found: C, 44.48; H, 4.31; N, 11.51.

The ORD spectrum in water showed a positive Cotton effect with a maximum at 274  $\text{m}\mu$  (molecular rotation +11,200°), zero rotation at 248  $\text{m}\mu$ , and a minimum at 234  $\text{m}\mu$  (molecular rotation –3900°).

Reaction<sup>15</sup> of 14 (27 mg) with 2,4-dinitrophenylhydrazine (20 mg) and concentrated hydrochloric acid (10  $\mu\text{l}$ ) in DMSO (1 ml) at room temperature for 2 hr gave the crystalline 2,4-dinitrophenylhydrazone, mp 174–177° from ethanol;  $\lambda_{\text{max}}^{\text{MeOH}}$  355  $\text{m}\mu$  ( $\epsilon$  21,400), 254  $\text{m}\mu$  ( $\epsilon$  18,700);  $\lambda_{\text{max}}^{\text{N}^+\text{MeOH}}$  437  $\text{m}\mu$  ( $\epsilon$  18,400), 250  $\text{m}\mu$  ( $\epsilon$  16,300), if taken immediately. On standing the 437- $\text{m}\mu$  peak slowly disappears and is replaced by peaks at 336 and 285  $\text{m}\mu$  (uracil?).

*Anal.* Calcd for  $\text{C}_{14}\text{H}_{14}\text{N}_6\text{O}_8$ : C, 42.64; H, 3.34; N, 19.90. Found: C, 42.68; H, 3.33; N, 19.00.

**Borohydride Reduction of 13 and 14.** (a) 3',5'-Di-O-trityl-2'-ketouridine (13, 339 mg) was treated at room temperature for 1 hr with sodium borohydride (300 mg) in ethanol (10 ml). The

mixture was then partitioned between chloroform and water and the organic phase was washed with water, dried, and evaporated leaving 340 mg of a white froth. Most of this (300 mg) was chromatographed on three 20  $\times$  100 cm silica plates using seven consecutive developments with carbon tetrachloride-acetone which cleanly separated two very close bands. The faster band was eluted with acetone giving 33 mg (11%) of 3',5'-ditrityluridine that was identical with an authentic sample by thin layer chromatography and by its infrared spectrum. Elution of the slower band gave 172 mg (57%) of chromatographically homogeneous di-O-trityl- $\beta$ -D-arabinofuranosyluracil (15)<sup>16</sup> which melted at 130° but could not be obtained crystalline;  $\lambda_{\text{max}}^{\text{MeOH}}$  261  $\text{m}\mu$  ( $\epsilon$  10,900);  $[\alpha]_D^{25} + 11.1^\circ$  (*c* 0.1, chloroform).

*Anal.* Calcd for  $\text{C}_{27}\text{H}_{24}\text{N}_4\text{O}_6$ : C, 77.47; H, 5.49; N, 3.93. Found: C, 76.73; H, 5.82; N, 3.93.

The ORD spectrum in dioxane showed a positive Cotton effect with a maximum at 280  $\text{m}\mu$  (molecular rotation +9900°) rotation at 272  $\text{m}\mu$ , and a minimum at 252  $\text{m}\mu$  (molecular rotation –18,400°). The nmr spectrum is recorded in Table I.

Detritylation of a small portion of the crude reduction product was effected by treatment with 80% acetic acid at 100° for 2 hr and, after removal of triphenylmethanol by chloroform extraction, the products were separated by borate electrophoresis. Qualitative elution of the spots showed the products to be 18% uracil and 82% 1-( $\beta$ -D-arabinofuranosyl)uracil (12).

(b) 2'-Ketouridine (6 mg) was treated for 30 min at room temperature with 7 mg of sodium borohydride in 80% ethanol. The material was then passed through a small column of 100 (H+) resin, evaporated to dryness, and evaporated four times with small portions of methanol. Borate electrophoresis and titative elution of the spots showed the products to be 10% uracil and 90% 1-( $\beta$ -D-arabinofuranosyl)uracil.

**Action of Alkali on 13.** 3',5'-Di-O-trityl-2'-ketouridine (400 mg) was dissolved in methanol (3.6 ml) and 1 *N* methanolic sodium hydroxide (0.4 ml) was added. Within a minute the solution turned yellow and then orange and a precipitate separated. After 10 min the mixture was cooled in ice, and the solid was collected by centrifugation. The precipitate was washed four times with methanol and dried *in vacuo* leaving a cream solid (23 mg) contained about 4 mg of uracil (ultraviolet and chromatographic) and no triphenylmethanol. The solid was washed with chloroform, and the soluble portion was evaporated leaving 12 mg of crystalline bis(triphenylmethyl) peroxide that was recrystallized from chloroform-methanol and had mp 186–188° (lit.<sup>18</sup> mp 188–190°). The nmr spectrum showed only aromatic protons and the spectrum (at 15 ev) showed intense peaks at *m/e* 259 (Ph, relative intensity 100%) and *m/e* 243 (relative intensity 73%, P).

*Anal.* Calcd for  $\text{C}_{28}\text{H}_{20}\text{O}_2$ : C, 88.00; H, 5.83. Found: C, 88.28; H, 5.62.

The methanol-soluble fraction from the alkaline reaction contained triphenylmethanol and uracil as shown by thin layer and paper chromatography.

**Action of Diazomethane on 13.** 2',5'-Di-O-trityl-3'-ketouridine (400 mg) was treated overnight in ether (10 ml) with an excess of diazomethane. Thin layer chromatography showed the presence of one major product and several minor ones. The major product was isolated by preparative thin layer chromatography using two developments with chloroform-benzene (1:1) giving a chromatographically homogeneous product that contained some aliphatic impurities by nmr spectroscopy. This product had  $\lambda_{\text{max}}^{\text{MeOH}}$  262  $\text{m}\mu$  which gradually changed to a broad maximum at 265–270  $\text{m}\mu$  in alkali during 10–15 min. Treatment of this product with sodium borohydride followed by detritylation with 80% acetic acid at 100° for 30 min gave a mixture of 1-( $\beta$ -D-xylofuranosyl)uracil (see below) and *N*-methyluridine (roughly 1:1) which were readily separated by paper chromatography using *n*-propyl alcohol-concentrated ammonium hydroxide-water (*R*<sub>f</sub>'s 0.75 and 0.70, respectively), in *n*-butyl alcohol-acetic acid-water (5:2:3) (*R*<sub>f</sub>'s 0.64 and 0.59), or by borate electrophoresis (mobilities of 1.03 and 0.80 relative to uridine). In all cases the products behaved identically with authentic samples.

**2',5'-Di-O-trityl-*N*-methyluridine.** 2',5'-Di-O-trityluridine (400 mg) was stored overnight in a mixture of chloroform (2 ml) and ether (4 ml) containing an excess of diazomethane. The mixture was then evaporated leaving a crystalline residue that was recrystallized from ether giving 2',5'-di-O-trityl-*N*-methyluridine (10 mg) mp 243–245°;  $\lambda_{\text{max}}^{\text{MeOH}}$  262  $\text{m}\mu$  ( $\epsilon$  7940), unchanged in alkali;  $[\alpha]_D^{25} + 90^\circ$  (*c* 0.1, chloroform).

*Anal.* Calcd for  $\text{C}_{28}\text{H}_{28}\text{N}_2\text{O}_5$ : C, 77.60; H, 5.70; N, 3.91. Found: C, 77.84; H, 5.62; N, 3.91.

ORD spectrum showed a positive Cotton effect with a maximum at 276  $m\mu$  (molecular rotation  $+28,500^\circ$ ), zero rotation at 256  $m\mu$ , and a minimum at 232  $m\mu$  (molecular rotation  $-40,500^\circ$ ). The ORD spectrum is similar to that of compound I for the nmr spectrum.

Hydrolysis with 80% acetic acid at 100° for 30 min gave *N*-methyluridine (19) that was chromatographically identical with the product from the action of diazomethane on uridine.

**5-Di-O-trityl- $\beta$ -D-xylofuranosyl)-*N*-methyluracil.** 1-(2,5-Di-O-trityl- $\beta$ -D-xylofuranosyl)uracil (11, 57 mg) was treated overnight with a mixture of chloroform (1 ml), methanol (1 ml), and ether (2 ml) in an excess of diazomethane. Evaporation of the solvent left a solid residue (63 mg) which was homogeneous by thin layer chromatography using chloroform-ethyl acetate (20:1). Crystallization from ether gave 43 mg of 1-(2,5-di-O-trityl- $\beta$ -D-xylofuranosyl)-*N*-methyluracil, mp 244–246°;  $\lambda_{max}^{MeOH}$  260  $m\mu$  ( $\epsilon$  9900), unchanged in alkali,  $[\alpha]_D^{25} +51.9^\circ$  ( $c$  0.1, chloroform).

*Anal.* Calcd for  $C_{44}H_{48}N_2O_8$ : C, 77.60; H, 5.70; N, 3.77. Found: C, 77.39; H, 5.64; N, 3.73.

The ORD spectrum in methanol showed a positive Cotton effect with a maximum at 273  $m\mu$  (molecular rotation  $+14,900^\circ$ ), zero rotation at 256  $m\mu$ , and a minimum at 236  $m\mu$  (molecular rotation  $-17,200^\circ$ ). The mass spectrum (15 eV) showed an intense peak at  $m/e$  126 corresponding to *N*-methyluracil.

Detritylation with 80% acetic acid at 100° for 30 min gave 1-( $\beta$ -D-xylofuranosyl)-*N*-methyluracil which ran as a single spot on paper chromatograms and on borate electrophoresis but was not isolated in crystalline form.

## An Electron Spin Resonance Study of the Radical Cations of Some *p*-Dialkoxybenzenes

W. F. Forbes, P. D. Sullivan, and H. M. Wang

*Contribution from the Department of Chemistry, University of Waterloo, Waterloo, Ontario, Canada. Received October 31, 1966*

**Abstract:** The electron spin resonance spectra of some *p*-dialkoxybenzene cation radicals in aluminum chloride–nitromethane have been investigated. The spectra can be interpreted by assuming *cis-trans* isomerism. The temperature dependence of the  $\beta$ -proton splitting constants, observed for the larger alkoxy compounds (ethoxy upwards), is explained by assuming hindered rotation of the alkoxy side chain.

In continuation of earlier work,<sup>1,2</sup> the cation radicals of some *p*-dialkoxybenzenes have been studied. The aim was to investigate how larger alkyl groups might affect properties such as *g* values, spin densities, hyperfine interactions, and the free energy difference between radical cations. These systems also illustrate some of the advantages of the aluminum chloride–nitromethane system for producing cation radicals.

### Experimental Section

Hydroquinone, *p*-dimethoxybenzene, *p*-diethoxybenzene, and butoxybenzene were commercially available samples, which were recrystallized several times. The other *p*-dialkoxybenzenes were prepared by the Williamson reaction<sup>3,4</sup> and purified by standard methods.

Sulfuric acid was best grade commercially available 98%  $H_2SO_4$ . Dideuterosulfuric acid was a commercially available sample (Fluka). Sulfuric acid spectra were determined in a 1M solution, ca. 0.04 ml of which was placed in a glass capillary tube which was then inserted in the spectrometer cavity. Nitromethane and aluminum chloride (anhydrous) were Fisher reagent grade. Nitromethane was dried ( $CaH_2$ ) and deoxygenated by drying ( $H_2SO_4$ ,  $Al_2O_3$ ) nitrogen gas through the solution, and by degassing under vacuum. Radical formation was carried out (cf. ref 5) in an inverted U tube (diameter ca. 8 mm), one arm of which was filled with aluminum chloride and the appropriate *p*-dialkoxybenzene (ca. 20 and 5 mg, respectively). The U tube was sealed to a vacuum line (ca. 0.5 mm) and nitromethane (ca. 1 mm) was distilled into the mixture. The reaction proceeded at room temperature, and the solution was subsequently transferred under vacuum to a capillary tube (diameter ca. 1 mm) which was sealed directly to one arm of the U tube. The capillary tube was

then placed in the esr cavity. If necessary, concentrations were varied by distilling solvent from one arm to the other.

Esr spectra were determined on a JES-3BX spectrometer at 100-kc/sec modulation using a field-selector unit. *g* values were obtained in a dual cavity with reference to Fremy's salt which was used as a secondary standard being first calibrated against the spectrum of anthracene (positive ion) for which an accurate *g* value ( $2.002565 \pm 0.000006$ ) is available.<sup>6</sup> The magnetic field was calibrated with both Fremy's salt ( $a_N = 13.07$  gauss)<sup>7</sup> and an nmr probe, and values of the splitting constants are believed accurate to  $\pm 0.5\%$  (for splitting constants  $>1$  gauss). The magnetic field was swept in both directions, and the first derivative spectra of the energy absorption were recorded in the relevant figures. Radical concentrations were estimated by overmodulating the signal and comparing it, under similar conditions, with a standard diphenylpicrylhydrazyl (DPPH) sample.

Spectra were simulated on an IBM 7040 computer, with a modified program kindly supplied by Dr. Lawrence C. Snyder of the Bell Telephone Laboratories.<sup>8</sup> The output data from the IBM 7040, in the form of punched cards, were plotted via an IBM 1710 computer. Approximate splitting constants were obtained directly from the observed spectra, usually by careful inspection of the wings. Sometimes, however, such direct measurement is not possible, and it is necessary to estimate splitting constants by measuring the total width of the spectrum. It is these values which are then slightly altered, within the experimental error, until a good simulated spectrum is obtained. Molecular orbital calculations were carried out by the self-consistent-field method of McLachlan<sup>9</sup> on an IBM 7040 computer, with a program kindly supplied by Dr. J. M. Fritsch<sup>10</sup> of the University of Kansas.

### Results and Discussion

***p*-Dihydroxybenzene.** The spectrum of the cation radical of hydroquinone in aluminum chloride–nitro-

<sup>a</sup> For nomenclature used in this and subsequent tables, see ref 1; also T = *trans* and C = *cis*, throughout.

ious conditions are shown in Table II; the data indicate no significant changes with temperature.

*p*-Diethoxybenzene. Figures 1a and 1c show the spectrum of the cation radical of *p*-diethoxybenzene in aluminum chloride-nitromethane. The spectrum can be interpreted in terms of two species A and B with splitting constants (in gauss) as follows: species A,  $a_{\text{H}} = 4.104$ ,  $a_{2\text{H}} = 2.922$ ,  $a_{4\text{H}} = 1.614$ , and  $a_{6\text{H}} = 0.152$ ; species B,  $a_{\text{H}} = 3.802$ ,  $a_{2\text{H}} = 2.660$ ,  $a_{4\text{H}} = 1.880$ , and  $a_{6\text{H}} = 0.152$ . Figures 1b and 1d show a simulated spectrum using these parameters and assuming a line width of 73 mgauss, a displacement of centers of 35 mgauss, and an intensity ratio A:B = 56:44.

The two species are assumed to correspond to *trans* and *cis* isomers. The assignment of the species to the isomers is made by analogy with previous calculations.<sup>1,2</sup> For the cation radicals of *p*-dimethoxybenzene<sup>1</sup> and hydroquinone,<sup>2</sup> empirical molecular orbital calculations following Stone and Maki<sup>12</sup> predicted that the species with the larger ratio of ring proton splitting constants is the *trans* isomer. On this basis, species A is the *trans* and B the *cis* isomer (see also later discussion). Assignments shown in Tables II-V are also based on these calculations.<sup>12a</sup>

In sulfuric acid, a similar but less intense signal was observed (see Table III for parameters). In  $\text{D}_2\text{SO}_4$ , a broad five-line spectrum (intensity ratio ca. 1:4:6:4:1) was obtained and, since rapid exchange of the ring protons is known to occur for compounds of this type,<sup>1</sup> the main splittings are ascribed to the four  $\text{CH}_2$  protons ( $\beta$ -protons) of the alkoxy groups. The splitting constants are, moreover, ca. 3.7 gauss, corresponding to the splitting constants of the four equivalent protons used in computing the spectrum shown in Figure 1b.

The temperature dependence of the spectrum (Table III) is illustrated in Figures 2a, 2b. The data show that the ring splitting constants remain approximately constant, but that the  $\beta$ -proton splittings vary significantly.

*p*-Di-*n*-propoxy-, *p*-Di-*n*-butoxy-, *p*-Di-*n*-pentoxy-, *p*-Di-*n*-hexoxy-, *p*-Di-*n*-heptoxy-, and *p*-Di-*n*-octoxybenzene. The spectra of all these cations proved to be

(12) E. W. Stone and A. H. Maki, *J. Chem. Phys.*, **38**, 1999 (1963).

(12a) NOTE ADDED IN PROOF. A recent study<sup>11</sup> of 2,3- and 2,5-dimethylhydroquinones which exist only in the *cis* and *trans* forms, respectively, afforded results consistent with the present assignments.

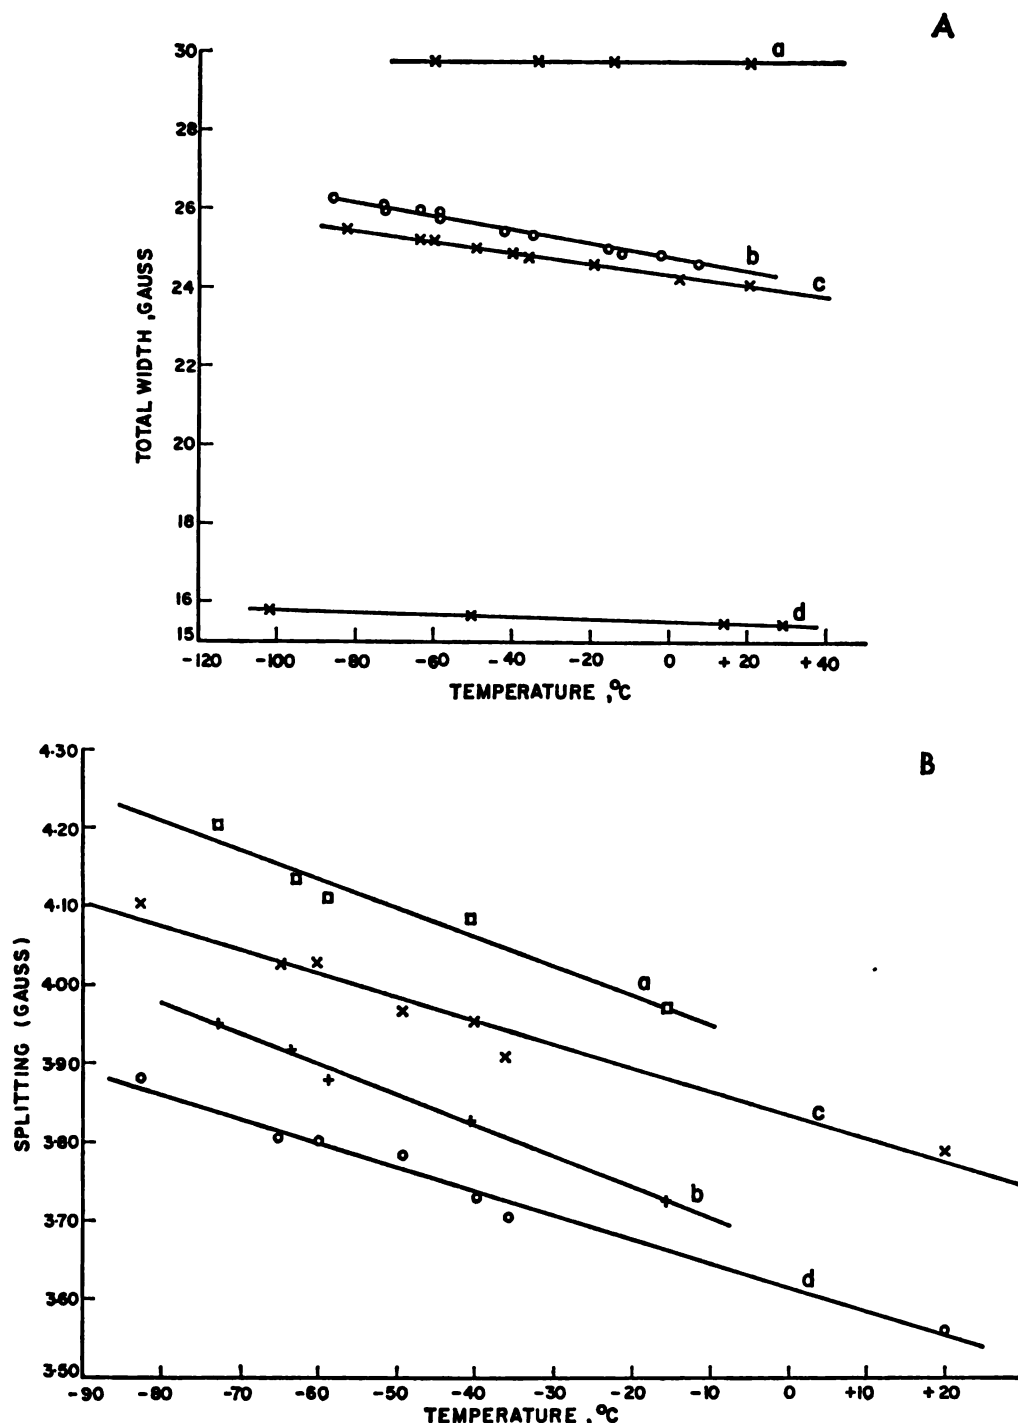

Figure 2. (A) Plots of the total width of the spectra against temperature for the cation radicals of (a) *p*-dimethoxybenzene, (b) *p*-di-*n*-butoxybenzene, (c) *p*-diethoxybenzene, (d) *p*-dihydroxybenzene. (B) Plots of the  $\beta$ -proton splitting constants against temperature for (a) *trans*- and (b) *cis*-*p*-di-*n*-butoxybenzene, and (c) *trans*- and (d) *cis*-*p*-diethoxybenzene, respectively.

similar under our conditions. Splitting constants are listed in Table IV. The spectrum of the *p*-di-*n*-octoxybenzene cation is shown in Figures 3a and 3c and a simulated spectrum with the following parameters is shown in Figures 3b and 3d. For species A (in gauss),  $a_{4H} = 4.168$ ,  $a_{2H} = 2.930$ ,  $a_{1H} = 1.622$ ,  $a_{4H} = 0.118$ ; for species B,  $a_{4H} = 3.968$ ,  $a_{2H} = 2.660$ ,  $a_{1H} = 1.880$ ,  $a_{4H} = 0.118$ ; a line width of 85 mgauss, a displacement of centers of 35 mgauss, and an intensity ratio A:B = 61:39 were assumed.

The temperature dependence of the splitting constants are shown in Table V and Figure 2, and again a change in the  $\beta$ -proton splitting constant is noted.

In sulfuric acid a weak signal is obtained, but the broadness of the lines precludes any accurate measurement of splitting constants. In  $D_2SO_4$ , a five-line spectrum (intensity ratio *ca.* 1:4:6:4:1) with a splitting constant of *ca.* 3.7 gauss was again obtained.

*p*-Diisopropoxybenzene. The spectrum of the cation radical of *p*-diisopropoxybenzene in sulfuric acid is shown in Figure 4b. It is not well resolved and a complete analysis has not been carried out, although the spectrum appears to consist of more than one component, consistent with the occurrence of *cis* and *trans* isomers. In  $D_2SO_4$ , only three broad lines, with a splitting constant of  $2.74 \pm 0.05$  gauss, are observed.

ues for the dialkoxybenzenes all fall within  $2.0037 \pm 0.00006$ , consistent with the pre- dicted generalization<sup>12</sup> that delocalization onto atom of an alkoxy group increases the *g* value 0.001 over the free spin value (2.0023). The rger value, relative to the hydroquinone cation ascribed to the electronic effects of the alkyl its.

ices between *cis* and *trans* Isomers. Assign- id *trans* isomers as indicated previously (see e VII), it is found that the percentage of the 1 increases with the size of the alkyl group in

C. Norman and R. J. Pritchett, *Chem. Ind. (London)*, 2040

Figure 5. Schematic representation of the equilibrium conformation of *p*-di-*n*-alkoxybenzene.

the order 50, 55, 56, 61 for the radicals of hydroquinone, *p*-dimethoxy-, *p*-diethoxy-, and *p*-di-*n*-propoxybenzenes, respectively. These percentages correspond to a free energy difference between the isomers of 0–250 cal/mole. Such an energy difference corresponds to a change in isomer ratio of only 3 or 4% over an 80° range and hence is not readily detected experimentally.

Tables II, III, IV, and VII also show that differences in  $\beta$ -proton splitting constants between the two isomers increase from ca. 0.15 gauss (for *p*-dimethoxybenzene) to ca. 0.22 gauss (for di-*n*-propoxybenzene). This may be related to the slightly greater displacement, observed between the centers of the two isomer spectra, for *p*-diethoxybenzene (0.035 gauss) than for *p*-dimethoxybenzene (0.029 gauss).<sup>1</sup> Possibly, increased steric interactions in the *cis* form cause some out-of-plane movement in the  $CH_2-O$  bond, leading to a relatively lower  $\beta$ -proton splitting constant and *g* value for the *cis* isomer. Such steric interactions might also be expected to make the *trans* isomer thermodynamically more stable, consistent with the previous assignment of *cis* and *trans* isomers (see earlier discussion). The above results are consistent with those obtained for other related examples of *cis-trans* isomerism.<sup>12,14</sup>

**Conformation of the Alkoxy Groups.** To explain the temperature dependence of the  $\beta$ -proton splitting constants, various torsional oscillations of the alkoxy side chain are considered. Since the methoxy proton splitting constants of the *p*-dimethoxybenzene cation radical show no temperature dependence, and the hydroxy protons of hydroquinone show only a small dependence, it is probable that torsional motion about the nuclear C–O bond can be neglected.

The discussion is therefore confined to the oscillations of the alkyl groups. Molecular models indicate that for the alkyl groups, steric interactions between the *ortho* ring proton and the alkyl protons may cause hindered rotation (see Figures 5 and 6). For a methoxy group (Figure 5;  $R = H$ ), there will be a threefold potential barrier to rotation about the O–C (alkyl) bond. Experimentally, all three methoxy protons are equiva-

lent, and, therefore, the barrier to rotation must be small. Since the CH<sub>3</sub> splittings are caused by a hyperconjugative mechanism, the maximum splitting will occur when the angle ( $\theta$ ) between the CH bond and the  $p\pi$  orbitals is 0° (see Figures 5 and 6). The actual

Figure 6. Schematic representation of the equilibrium conformation of *p*-diisopropoxybenzene.

form of the dependence of the splitting constant ( $a_{\beta H}$ ) on  $\theta$  may be postulated as (cf. ref 15),

$$a_{\beta H} = (B_0 + B_2 \cos^2 \theta) \rho_0 \pi$$

where  $\rho_0 \pi$  = spin density on the oxygen atom,  $B_0$  is a small constant, and  $B_2$  has been found to be of the order 30–45 gauss for a number of radicals. For the freely rotating methyl group, the average value of  $\theta = 45^\circ$  gives  $\langle \cos^2 \theta \rangle = 1/2$ . Using a value of  $\rho_0 \pi = 0.1758$ , taken from MO calculations,<sup>1,16</sup>  $B_0 + B_2 = 38.5$  gauss, in reasonable agreement with earlier work. This, together with the observed sharp lines and with the absence of line-width effects expected from a non-freely rotating methyl group,<sup>17</sup> suggests that the rotation is reasonably unhindered.

(15) M. C. R. Symons, *Advan. Phys. Org. Chem.*, **1**, 325 (1963), and references cited there.

(16) We have since improved the MO calculations in ref 1 by using a slightly different set of parameters.

For the *p*-diethoxybenzene cation radical, increased steric interactions between the  $\beta$ -ethyl group and the *ortho* ring protons are expected. This should lead to a potential energy diagram of the form schematically shown in Figure 7. The minimum energy conforma-

Figure 7. Schematic energy diagram for rotation about the O-C (alkyl) bond of *p*-diethoxybenzene.

tion will be that shown in Figure 5 ( $R = CH_3$ ). If this is the actual conformation, then  $2a_{\beta-CH_2}$  (diethoxy) =  $3a_{\beta-CH_2}$  (dimethoxy), but experimentally  $2a_{\beta-CH_2} = 8.05$  gauss and  $3a_{\beta-CH_2} = 10.17$  gauss. Stone and Maki,<sup>18</sup> in their treatment of the systems  $RRCHAr\cdot$  and  $RCH_2Ar\cdot$ , have pictured the physical situation as one in which there is torsional oscillation about the equilibrium conformation. The form of this motion is assumed to be sinusoidal, leading to an equation for  $a_{\beta-H}$  of the form<sup>18</sup>

$$a_{\beta-H} = [B_0 + B_2 \cos^2 (\theta_0 + \phi \sin 2t/\tau)] \rho_0 \pi$$

where  $\theta$  = the equilibrium angle,  $\phi$  = torsional amplitude, and  $\tau$  is the period of oscillation. Provided that  $\tau$  is rapid compared to the hyperfine interaction, the equation may be averaged over time. If  $\tau$  is of the same order as the hyperfine interaction (ca.  $7 \times 10^{-8}$  sec), the lines will be broadened (see also discussion for *p*-diisopropoxybenzene).

From Figure 5,  $\theta = 30^\circ$ , and hence, by comparison with Figure 2 of ref 18, we can estimate that at a tem-

(17) J. H. Freed and G. K. Fraenkel, *J. Am. Chem. Soc.*, **86**, 3477 (1964).

(18) E. W. Stone and A. H. Maki, *J. Chem. Phys.*, **37**, 1326 (1962).

perature of  $-60^\circ$ ,  $\phi = 50^\circ$  for the *p*-diethoxybenzene cation radical. As the temperature decreases,  $\phi$  would be expected to decrease, leading to the observed increase in the  $\beta$ -proton splitting constant.

For the larger *p*-di-*n*-alkoxybenzene cation radicals, a similar temperature dependence would be expected, and is observed (see Table V). The torsional amplitude,  $\phi$ , would be expected to decrease with increased size of the substituent, leading to an increased  $\beta$ -proton splitting constant, and this is observed for the *n*-propoxy compound (*cf.* Tables III and IV). Further lengthening of the side chain does not give rise to any significant changes, presumably because the effective size of the substituent is not altered on passing from *n*-propyl to *n*-octyl (*cf.* also ref 19).

Molecular models of the *p*-diisopropoxybenzene cation radical (see Figure 6;  $R_1 = R_2 = \text{CH}_3$ ) indicate an equilibrium conformation in which  $\theta \approx 90^\circ$  for the lone CH proton, suggesting  $a_{\beta\text{-H}} = 0$  in the absence of torsional oscillation. Increased torsional oscillation with temperature would be expected to lead to an in-

crease in the value of  $a_{\beta\text{-H}}$ . Although the spectrum is not well resolved, because of line broadening, such an increase is indeed observed (see section on *p*-diisopropoxybenzene). The experimentally obtained value of  $a_{\beta\text{-H}} = \text{ca. } 2.60$  is consistent with a torsional amplitude of about  $57^\circ$ .

The experimentally observed line-width increase of the *p*-diisopropoxybenzene cation compared with that of the other *p*-dialkoxybenzenes (*ca.* 250 mgauss to 70 mgauss) could be explained if the period of torsional oscillation,  $\tau$ , in the isopropoxy compound was of the same order as the hyperfine splitting ( $\sim 10^{-7}$  sec), thus leading to line broadening. Alternatively, it may be caused by small unresolved splittings of the  $\beta\text{-CH}_3$  groups.

In the above discussion, changes because of the inductive effect of substituents have been ignored. The justification for this is based on the near-constancy of (i) the *g* values (see Table VI) and (ii) the ring proton splitting constants.

## Mass Spectrometry in Structural and Stereochemical Problems. CXXX.<sup>1</sup> A Study of Electron Impact Induced Migratory Aptitudes<sup>2</sup>

Peter Brown<sup>3</sup> and Carl Djerassi

Contribution from the Department of Chemistry, Stanford University, Stanford, California 94305. Received January 6, 1967

**Abstract:** The electron impact induced decarboxylation of aryl methyl and aryl phenyl carbonates has been investigated in some detail, using low-voltage and isotope-labeling techniques, and by studying substituent effects on the rate of loss of carbon dioxide. In the substituted-aryl methyl compounds, exclusive methyl group migration is observed, whereas in the aryl phenyl carbonates, competition between the two possible itinerant moieties is apparent, and aryl group relative migratory aptitudes can be assigned. In addition, the substituent dependence of the abundance of the  $\text{CH}_2\text{OCO}^+$  ion from  $\alpha$  cleavage in aryl methyl carbonates has been correlated with Hammett  $\sigma$  values.

Of the unimolecular processes energetically accessible to ions generated by electron impact, that of skeletal rearrangement<sup>4</sup> (in compounds other than hydrocarbons) has only recently been accorded recognition as a relatively common possibility. Despite the elegant application<sup>5-7</sup> of accepted physical organic techniques to simple mass spectral bond cleavages, no

similar studies on systems undergoing alkyl or aryl group migrations have as yet been reported. We therefore elected to examine in some detail the necessary requirements for methyl migration in aryl methyl carbonates<sup>8</sup> (I  $\rightarrow$  III) and aryl *vs.* phenyl migration in aryl phenyl carbonates<sup>8</sup> (II  $\rightarrow$  IV), each with concomitant ejection of carbon dioxide as the neutral species.

M - 44

The rearrangement reactions proved to be relatively facile, giving rise to intense peaks in the 70-ev spectra.<sup>3</sup> Reduction of the ionizing voltage to approxi-

Figure 1. Correlation of the  $M - 44$  ion III intensity in the 12-ev mass spectra of substituted aryl methyl carbonates I with  $\sigma^+$ . Least-squares slope ( $\rho$ ) = +0.67, standard deviation = 0.18.

mately 12 ev<sup>9</sup> greatly simplified the spectra, the peaks due to the molecular ion and the  $M - 44$  species together accounting for at least 95% of the total ionization ( $\Sigma_{40}$ ) with compounds I, and at least 60%  $\Sigma_{40}$  with compounds II.<sup>10</sup> Thus by variation of the nuclear substituents X in I and II, it was hoped to secure data pertaining to both the electronic nature of the migrating group and of the receptor site in these particular systems.

**Aryl Methyl Carbonates.** The results obtained in the electron impact induced<sup>11</sup> decarboxylation of substituted aryl methyl carbonates (I  $\rightarrow$  III) are presented as a Hammett<sup>5a,12</sup> plot in Figure 1, using relationship 1 as modified by McLafferty<sup>5a</sup> to permit kinetic evaluation of mass spectra. Thus  $Z = [A]/[M]$ , where [A] and [M] are the relative abundances of the peaks due to the  $M - 44$  fragment (III) and the molecular ion respectively, and the subscripts X and H refer to substituted and parent compounds, respectively. In these

$$\log(Z_X/Z_H) = \rho\sigma \quad (1)$$

systems, the  $M - 44$  species (III) have compositions dependent on the substituent X, and at normal ionizing voltages (i.e., 70 ev), further decompositions of III will also depend on the nature of X. At lower voltages, however (i.e., 12 ev), all peaks in the spectra of compounds of type I except for the  $M - 44$ /molecular ion pair<sup>13</sup> are absent, indicating that competing and consecutive reactions have been totally eliminated. The

relative peak heights at 12 ev were therefore employed exclusively in all calculations of relative kinetics of the rearrangement processes.

Although the correlation (Figure 1) displays considerable scatter, sufficient substituents were employed to show that a very definite trend exists. Thus in general, electron-attracting groups increase the rate of the reaction I  $\rightarrow$  III, and electron-releasing substituents depress it. Use of  $\sigma$  constants<sup>15a</sup> did not obviously improve the quality of the fit over that obtained with  $\sigma^+$  values,<sup>15b</sup> and the latter appear in Figure 1.<sup>15c</sup> The least-squares value of the slope ( $\rho = +0.67$ ) was obtained by computer.

In order to elucidate further<sup>8</sup> the mechanism of electron impact induced decarboxylation of compounds of type I, the <sup>18</sup>O-labeled carbonates V and VI (X = H) were prepared. In the mass spectrum of V, the rearrangement peak moved cleanly to  $m/e$  110 (a,  $M - 44$ ),

whereas with VI (X = H) it remained<sup>8</sup> entirely at  $m/e$  108 (b,  $M - 46$ ). These observations are consistent

(15) (a) J. Hine, "Physical Organic Chemistry," McGraw-Hill Book Co., Inc., New York, N. Y., 1962, Chapter 4. (b) H. C. Brown and Y. Okamoto, *J. Am. Chem. Soc.*, **80**, 4979 (1958). (c) A referee has pointed out that the rate terms for *meta* and *para* electron-donating substituents are nearly the same. A similar observation had been made earlier<sup>16</sup> with substituted phenoles, and the suggestion had been made that equilibration of substituents occurred in the molecular ion. If such a rearrangement is also operating in our compounds with electron-donating substituents, then the Hammett correlations in Figures 1, 3, and 4 would be considerably improved.

preferential charge location<sup>16</sup> in the molecular ion ie phenoxy group, followed by exclusive methylation to the electron-deficient site. The data also put isomerizations of the molecular ion analogous those encountered<sup>17</sup> in methyl phenyl thioncarbamates. The mass spectra of the <sup>18</sup>O-labeled compounds VI (X = OCH<sub>3</sub>) and VI (X = CN) were also and total loss of the heavy isotope as carbon dioxide-<sup>18</sup>O indicates that only methyl migration is ring, regardless of the electronic nature of the substituent X.

The preference for the phenoxy oxygen atom (e.g., a) over the *ortho* position of the aromatic ring → c) as the receptor site for methyl migration has already been expressed.<sup>8</sup> Additional evidence against operation of a six-center transfer (VII → c) is contained

the per cent total ionization figures for the M - 44 rearrangement peak in the spectra of the isomeric 3,4-, and 2,6-dimethylphenyl methyl carbonates (VIII, and X, respectively, Table I). It is clear that there is an abnormal steric effect intervening in the case of  $\pi$  X.<sup>18</sup>

		$\Sigma_{44}$
	R <sub>1</sub> = R <sub>2</sub> = CH <sub>3</sub> ; R <sub>3</sub> = R <sub>4</sub> = H	6.1
	R <sub>1</sub> = R <sub>4</sub> = H; R <sub>2</sub> = R <sub>3</sub> = CH <sub>3</sub>	4.4
	R <sub>1</sub> = R <sub>3</sub> = H; R <sub>2</sub> = R <sub>4</sub> = CH <sub>3</sub>	4.6

the evidence of a more compelling nature for representative M - 44 species from decarboxylation of aryl methyl carbonates I as the aryl methyl ether molecular ion was adduced by comparison of the metastable peaks observed in the mass spectra of the parent carbonate (I, X = H) and anisole (III, X = H). Not only the spectra of these two compounds extremely

It is assumed that electron impact can displace an electron from the neutral molecule, and that the resulting radical ion decomposes extremely rapidly to a state in which the net charge is stabilized distributed over the whole system, and that this type of molecular ion decomposes into the major ions of the mass spectrum. The closest approximation of "charge localization" involves the writing of apparently favorable resonance structures of an ion, and then the formal electron deficiency to rationalize subsequent fragmentation.

Thus the single electron deficiency of the molecular ion of methyl carbonate can be accommodated in more low energy resonance of the phenoxy rather than the methoxy portion of the molecule (VII and VI are preferred formalisms). With aryl phenyl carbonates, charge distribution in the molecular ion is expected to be somewhat symmetrically disposed on either side of the carbonyl group, and sensitive to the electronic nature of aromatic substituents.

J. B. Thomson, P. Brown, and C. Djerassi, *J. Am. Chem. Soc.*, **88**, 49 (1966).

C. P. Lewis, *Anal. Chem.*, **36**, 176 (1964), reports that 2,6-disubstitution does not deter an analogous skeletal rearrangement involving loss of carbon dioxide in ethyl N-phenylcarbamate.

similar<sup>8</sup> below  $m/e$  108 (M - 44 for I, X = H) (except for the presence of an additional peak at  $m/e$  59 in I, X = H, due to the CH<sub>3</sub>OCO<sup>+</sup> species), but the positions, relative intensities, and peak shapes<sup>19</sup> of all six metastable peaks<sup>20</sup> in the anisole spectrum (Figure 2b) are faithfully reproduced in that of methyl phenyl carbonate (Figure 2a). This correspondence is demonstrated in a particularly striking fashion in Figures 2a and 2b, which show the direct record obtained by means of a logarithmic transfer recorder,<sup>21</sup> operating in conjunction with an Atlas CH-4 mass spectrometer.

Two of the more plausible mechanisms consistent with the labeling results that may be entertained for the M - 44 rearrangement process are depicted in Schemes I and II.

Scheme I

Scheme II

In Scheme I, methyl radical migration to electron-deficient phenoxy oxygen (I → da) is envisaged initially, followed by homolysis of the O-CO bond and loss of carbon dioxide (da → III). If the process is concerted, i.e., methyl migration and carbon dioxide ejection occurring simultaneously, then the situation is described by Scheme II. There appear to be no authenticated precedents for 1,3-methyl radical migrations outside of mass spectrometry.<sup>22</sup> Even 1,2-methyl radical shifts are rare,<sup>23,24</sup> although 1,2 migration as a potential carbanion to an electrophilic center is much more common<sup>25</sup> (e.g., Wagner-Meerwein, Baeyer-Villiger, pinacol rearrangements).

Scheme II envisages a four-center transition state db, and accounts satisfactorily for the observed positive slope of the Hammett plot (Figure 1) by invoking a shift of the methyl group with its bonding pair of elec-

(19) T. W. Shannon and F. W. McLafferty, *J. Am. Chem. Soc.*, **88**, 5021 (1966), call attention to the fact that ions identical in structure and energy should exhibit identical decomposition reactions and, therefore, the spectra should also show the same metastable peaks, with identical peak shapes and intensities relative to the parent ion.

(20) These appear at  $m/e$  80.0 (93<sup>2</sup>/108),  $m/e$  57.9 (79<sup>2</sup>/108),  $m/e$  56.4 (78<sup>2</sup>/108),  $m/e$  45.4 (65<sup>2</sup>/93),  $m/e$  33.8 (51<sup>2</sup>/77), and  $m/e$  23.4 (39<sup>2</sup>/65). The only additional metastable peak discernible in the carbonate spectrum (Figure 2a) occurs at  $m/e$  76.8 (108<sup>2</sup>/152), and corresponds to the loss of carbon dioxide from the molecular ion.

(22) A formal 1,3-methyl shift has been detected in the pyrolysis of diazoisofenchone by P. Yates and S. Danishefsky, *J. Am. Chem. Soc.*, **84**, 879 (1962), although the electronic nature of the migrating species is not known.

(23) C. Walling, "Molecular Rearrangements," P. de Mayo, Ed., Interscience Publishers Inc., New York, N. Y., 1963, p 416.

(24) C. McKnight and F. S. Rowland, *J. Am. Chem. Soc.*, **88**, 3179 (1966), report tritium-labeling evidence for a 1,2-methyl radical migration pathway in the reaction of triplet methylene with *trans*-2-butene.

(25) H. E. Zimmerman and A. Zweig, *J. Am. Chem. Soc.*, **83**, 1196 (1961), have provided a rationale for 1,2 shifts of methyl and phenyl groups based on MO calculations.

Figure 2. a. Logarithmic transfer recorder trace of the low-resolution mass spectrum of methyl phenyl carbonate. b. Logarithmic transfer recorder trace of the low-resolution mass spectrum of anisole.

trons to the most electrophilic site available. Thus in the transition state, the partial charge on the phenoxy oxygen will become less positive in character, and bond forming to the methyl group will be more advanced than bond breaking of the O-CO bond. Scheme I, on the other hand, would predict a negative  $\rho$  value if the rate-determining transition state lies between I and da, since its formation would be inhibited by electron-withdrawing substituents and facilitated by electron-releasing groups.

Other instances of electron impact induced group migrations accompanied by carbon dioxide expulsion have been documented.<sup>4</sup> These reactions are most prevalent in gaseous ions where an especially electron-deficient center is developed adjacent to the carbonyl moiety, and can then be visualized as involving a nucleophilic 1,3-group shift to that positive site.

For example, alkyl group migration apparently occurs only after initial cleavage has generated a full positive charge in the vicinity of the migration receptor site in trimethylsilyl esters of some fatty acids<sup>26</sup> (XI), in ethyl N-ethylcarbamate<sup>17</sup> (XII), in dialkyl carbonates such as XIII,<sup>8</sup> and with benzyloxycarbonyl derivatives of certain amino acid esters<sup>27</sup> (XIV).

Other processes that can be rationalized similarly are the successive loss of a methyl group and hydrogen

cyanide from amidines,<sup>28</sup> and of a methyl group a formaldehyde from formaldehyde acetals of second- and tertiary alcohols<sup>29</sup> and also from the trimethyl silyl derivative of benzyl alcohol.<sup>30</sup>

3. Correlation of the  $m/e$  59 ion (e) intensity in the 70-ev mass spectra of substituted aryl methyl carbonates I with  $\sigma$ . Least-squares  $\rho = +1.43$ , standard deviation = 0.18.

should be pointed out, however, that group migration with concomitant expulsion of carbon dioxide can operate in radical ions where initial  $\alpha$  cleavage is inhibited, for example, in esters of  $\alpha,\beta$ -unsaturated <sup>31</sup> aryl methyl and aryl phenyl carbonates,<sup>8</sup> and N-arylcabamates.<sup>32</sup> A characteristic peak appears at  $m/e$  59 in the 70-ev spectra of all aryl methyl carbonates I, consistently on an ion of composition  $C_7H_5O_2^+$  (e). At 12 ev, the process is completely suppressed. The contribution of fragment e to the higher voltage total ionization energy is dependent on the aryl substituent X, ranging from 1.8%  $\Sigma_{40}$  (I, X =  $p$ -OCH<sub>3</sub>) to 18.0%  $\Sigma_{40}$  (I, X =  $p$ -NO<sub>2</sub>). The relevant data (in which the abundance of fragment e compared with that of the molecular ion I) are reduced as a Hammett<sup>33,34</sup> plot in Figure 3.

In this case,  $\sigma$  constants<sup>35a</sup> gave a correlation with less scatter than that obtained using  $\sigma^+$  values.<sup>35b</sup> It is interesting to compare the slope of  $\rho = +1.43$  for the reaction I  $\rightarrow$  e with that of  $\rho = +0.78$  for the formation of  $\alpha$  cleavage ion f in substituted acetophenones,<sup>36</sup> and  $\rho = +0.67$  for the production of e (59) from substituted methyl benzoates.<sup>7</sup> This suggests that bond breaking has proceeded to a greater extent in the transition state for cleavage in the car-

bonates (I  $\rightarrow$  e) compared with the acetophenones (XV  $\rightarrow$  f) and the methyl benzoates.

It is pertinent at this point to comment briefly on the application of Hammett  $\sigma\rho$  studies to electron impact induced rearrangements and fragmentations. In ground electronic state (thermal) reactions, those processes which develop relatively large fractional charges in the transition state (compared to the reactants) at the reaction site exhibit the largest numerical reaction constants<sup>33</sup> ( $\rho$ ), whereas processes in which charge is merely redistributed in the transition state are characterized by small  $\rho$  values.<sup>34</sup>

In conventional mass spectrometry, one is dealing with gaseous unimolecular endothermic reactions, where the transition state may be expected to resemble the products rather than the reactant,<sup>35</sup> and where both reactant and transition state bear a full positive charge. This description allows the possibility of relatively large reaction constants. On the other hand, it has been pointed out<sup>36</sup> that the transition state for a gas-

(33) For example, quoted in ref 15b,  $\rho = -4.67$  for SN1 solvolysis of *t*-cumyl chlorides in ethanol at 25°, and  $-4.74$  for ionization of substituted benzylidene alcohols. K. Wiberg and T. M. Shryne, *J. Am. Chem. Soc.*, **77**, 2774 (1955), report  $\rho = -3.86$  and  $-3.56$  for the thermal rearrangement of  $\alpha$ -arylethyl chlorocarbonates in dioxane and toluene, respectively.

Figure 4. Correlation of the  $M - 44$  ion IV intensity in the 12-ev mass spectra of substituted aryl phenyl carbonates II with  $\sigma^+$ . Least-squares slope ( $\rho$ ) = +0.34, standard deviation = 0.18.

phase heterolysis will be considerably less ionic than the equivalent process in solution, due to the absence of external solvation. Applying this argument to gaseous ions under low pressure leads to the prediction of relatively small reaction constants. Insufficient data are available at present, but  $\rho = +1.43$  for the reaction  $I \rightarrow e$  represents the largest numerical reaction constant obtained so far.

**Aryl Phenyl Carbonates.** The high- and low-voltage mass spectra of diphenyl carbonate<sup>8,10</sup> (II, X = H) and of its substituted analogs all display important peaks due to the expulsion of carbon dioxide ( $II \rightarrow IV$ ).<sup>11</sup> As with the aryl methyl compounds (I), the  $M - 44$  process persists at low voltage, at the expense of all other competing reactions. To avoid approaching the threshold of the appearance potential<sup>10</sup> of the  $M - 44$  species IV too closely, spectra for kinetic treatment were again recorded at 12 ev.

Group migration to oxygen as the receptor site is also envisaged in the aryl phenyl series, by analogy with methyl migration in the aryl methyl carbonates I. In support of this contention may be cited the fact that the mass spectrum of diphenyl carbonate (II, X = H) contains all the peaks characteristic of diphenyl ether (IV, X = H) itself, and especially all the metastable peaks<sup>17</sup> displayed by diphenyl ether, with identical peak shapes and abundances,<sup>18</sup> relative to the molecular ion. It should be noted, however, that although there is some positive evidence for representing the  $M - 44$  radical ion from diphenyl carbonate and the molecular ion of diphenyl ether by the same structure (formalism IV, X = H), the rearrangement ion is apparently formed with some excess energy. The heats of formation of  $C_{12}H_{10}O^+$  have been reported<sup>10</sup> as 257 and 220 kcal/mole for diphenyl carbonate and diphenyl ether, respectively.

(37) These appear at  $m/e$  140.0 (141<sup>1</sup>/142),  $m/e$  118.6 (142<sup>1</sup>/170),  $m/e$  93.8 (115<sup>1</sup>/141),  $m/e$  50.9 (93<sup>1</sup>/170),  $m/e$  33.8 (51<sup>1</sup>/77), and  $m/e$  23.4 (39<sup>1</sup>/65), and were observed as before employing the logarithmic transfer recorder.

Since decarboxylation can occur with either aryl or phenyl group migration, <sup>18</sup>O-labeling of the phenoxy moiety was effected (XVI). Thus aryl migration then

furnishes the  $M - 44$  ion ga (with label retention), whereas phenyl migration affords the  $M - 46$  species gb. In this way, the over-all rate of decarboxylation for each aryl phenyl carbonate can be divided into two partial rates, for aryl and phenyl group migration, respectively.

In Figure 4 the kinetic data for phenyl migration ( $XVI \rightarrow gb$ ) are correlated with  $\sigma^+$  values,<sup>18b</sup> the use of which gave a plot with slightly less scatter than did  $\sigma$  constants.<sup>18a</sup> The smaller slope of  $\rho = +0.34$  for phenyl compared to  $\rho = +0.67$  for methyl migration could be interpreted as a lesser dependence on substituent effects at the receptor site for shifting of the more electronically versatile phenyl group, but the uncertainty in the magnitude of the slope in Figure 4 is rather large.

Two possible mechanisms for decarboxylation by phenyl migration are described in Schemes III and IV. Scheme III is analogous to Scheme I for aryl methyl carbonates I, and is considered less probable on the same grounds. Making the reasonable assumption

that the rate-controlling transition state would lie between II and ha, a negative  $\rho$  value for the Hammett correlation would be anticipated. In this system, therefore, the occurrence of phenyl bridging (as in a  $\sigma$ -bonded intermediate such as ha) appears unlikely.

Scheme III

Scheme IV is the phenyl analog of Scheme II for the methyl compounds I, and as before, satisfactorily accounts for the positive  $\rho$  value obtained. In view of the small numerical value of  $\rho$ , and the as yet unknown range of reaction constant magnitudes for a representative cross section of electron impact induced processes, it is perhaps too early at present to assess finally the significance of  $\rho$  in this case, except to note that it has a positive sign.

Scheme IV

**Relative Migratory Aptitudes of Aryl Groups.** In addition to revealing the electronic requirements at the receptor site for migration, the model carbonate system also produced information pertaining to the nature of the itinerant group. Despite the wide-spread occurrence in mass spectrometry of rearrangement processes involving intramolecular transfer of atoms or groups other than hydrogen,<sup>4</sup> the literature to date still contains only a few isolated references to the relative migratory propensities of the peripatetic groups.

In the mass spectra of trimethylsilyl esters of substituted benzoic acids XVII, an approximate correlation between relative abundance of the rearrangement ion ic and the electronic character of the aromatic substituent X was noted.<sup>38</sup> In fact, electron-donating groups X increased the extent of rearrangement by aryl migration (ia  $\rightarrow$  ib  $\rightarrow$  ic), relative to electron-withdrawing substituents. However, the intensity of a mass spectral peak depends on the rates of decomposition of the ions contributing to it, as well as on their rates of formation, and unfortunately both sets of rates are very probably dependent on X in this instance.

In a study of the mass spectra of diaryl sulfones, evidence was adduced<sup>38</sup> for the operation of an aryl rearrangement process XVIII  $\rightarrow$  ja, jb. In a series of unsymmetrical diaryl sulfones, preferential migration of the more nucleophilic aryl group was consistently observed, although it was clearly recognized that different rates of decomposition of different rearrangement ions contributed to the lack of internal consistency in the formulation of a relative migratory aptitude scale.

It has been reported recently<sup>39</sup> that phenyl migration is more favored than a methyl shift in the fragmentation of 1-phenyl-2-d-epoxypropane (XIX). This estimate was made by comparing the relative intensities of the extremely small peaks at  $m/e$  106 and 105, due to species kb and kd, respectively, and is uncomplicated by the absence of any necessity to allow for different rates of further decomposition of the rearrangement ions (kb, kd), apart from a H/D isotope effect.

In the aryl phenyl carbonate system, aryl migration (XVI  $\rightarrow$  ga) and phenyl migration (XVI  $\rightarrow$  gb) both furnish formally the same aryl phenyl ether radical ion, except for the isotope label in ga. Therefore, any further minor decomposition<sup>40</sup> suffered by the rearrangement ions at 12 eV is independent of which group has shifted. The extent of rearrangement occurring

<sup>a</sup> This ratio was found to be the same at 70, 15, and 12 ev within experimental error. <sup>b</sup> See ref 15b. <sup>c</sup> Acid-catalyzed rearrangement. <sup>d</sup> See ref 43.

by aryl (XVI  $\rightarrow$  ga) and phenyl (XVI  $\rightarrow$  gb) migration as determined by <sup>18</sup>O labeling is shown in Table II. In 12 out of 15 examples, the over-all rate of decarboxylation decreases upon introduction of either electron-withdrawing or electron-releasing substituents, and is at a maximum when X = H.

This observation can be rationalized on the basis of charge distribution<sup>16</sup> in the molecular ion, and by taking account of the relative basicities<sup>43</sup> of the aryl groups concerned. In an unsymmetrical aryl phenyl carbonate molecular ion (e.g., that of II), the positive charge will be unsymmetrically partitioned on either side of the carbonyl group. The direction and magnitude of this charge asymmetry will depend on the electronic character of the substituent X. The relative contributions of resonance forms IIa (preferred for electron-attracting groups X) and IIb (preferred for electron-donating substituents) provide an approximate description of the situation.

Thus simply on charge localization grounds, aryl migration to the most electrophilic center might be predicted to preponderate (see arrows in IIa) for X = + $\sigma$  groups, and phenyl migration (see arrows in IIb) for X = - $\sigma$  substituents. In fact, the reverse situation obtains (Table II), indicating that the nucleophilicity of the migrating group is critical. The more nucleophilic entity is preferentially itinerant (arrows, IIb) when X = + $\sigma$  substituents (e.g., *p*-NO<sub>2</sub>, *p*-CN, *p*-F, *p*-Br, *p*-CO<sub>2</sub>CH<sub>3</sub>, *o*-OCH<sub>3</sub>), although the rate of migration is lower than in diphenyl carbonate (II, X = H) itself, since IIb is a higher energy resonance form of the molecular ion. Conversely, when X = - $\sigma$  groups

(42) As for example toward electrophilic substitution.<sup>4b</sup>

(e.g., CH<sub>3</sub>, *p*-C<sub>6</sub>H<sub>5</sub>, *m*- and *p*-OCH<sub>3</sub>), migration of the more basic aryl moiety (arrows, IIa) is preferred, again at a lower rate than when X = H, since IIa is now a higher energy resonance contributor.

Charge localization and nucleophilicity, therefore, oppose each other in determining the over-all migratory propensities of aryl groups in this particular system. The more basic aryl groups, with electron-releasing substituents, excel at both charge localization and migration. Conversely, the less nucleophilic aryl groups, with electron-withdrawing substituents, are poorer at both charge localization and migration, and the relative migratory aptitudes tend to be leveled by internal compensation of these two effects.

The resulting aryl group migratory aptitudes (Table II, column 6) for the electron impact induced decarboxylation reaction (1,3 migration) are to be compared with those for acid-catalyzed rearrangement of substituted benzpinacols<sup>44</sup> (1,2 migration) (Table II, column 7). It can be seen that the electron impact process migration propensities follow only in an extremely qualitative sense those observed for the carbonium ion process in solution.<sup>44</sup> Further studies are in progress to determine the relative migratory aptitudes of both aryl and alkyl groups in other mass spectral rearrangement reactions.

## Experimental Section

**Mass Spectra.** The low-resolution mass spectra of the aryl methyl carbonates I were obtained by Drs. A. M. Duffield and J. K. MacLeod, using an Atlas CH-4 instrument and operating under the following conditions: ionizing voltage 70, 15, and 12 ev, inlet temperature 70°, AN-4 ion source at 180°. Low-resolution spectra of the aryl phenyl carbonates II were recorded by Mr. N. S. Garcia, employing a CEC 21-103 machine equipped with an all-glass heated inlet system at 200° and ion source temperature 250°. All high-resolution mass measurements were secured by Mr. R. G. Ross, with an AEI MS-9 double-focusing mass spectrometer of apparent resolution 1 part in 15,000, and fitted with an all-glass heated inlet system at 200°, and ion source temperature 250°.

For quantitative relative abundance measurements, the spectra of each series of compounds I and II were run sequentially under identical operating conditions. At least duplicate determinations were made for each individual compounds, and it was found that peak heights were reproducible to within  $\pm 1\%$ .

The ALGOL computer program for least-squares treatment of the Hammett plot data was kindly supplied by Dr. J. I. Brauman.

**Preparation of Carbonates.** Unlabeled aryl methyl carbonates and aryl phenyl carbonates were prepared as before,<sup>8</sup> from methyl and phenyl chloroformates, respectively. <sup>18</sup>O-Labeled aryl methyl

## Mass Spectra of Nucleic Acid Derivatives. II. Guanine, Adenine, and Related Compounds<sup>1a</sup>

Jerry M. Rice<sup>1b</sup> and Gerald O. Dudek<sup>1c</sup>

*Contribution from the National Cancer Institute, National Institutes of Health, Bethesda, Maryland 20014, and the Department of Chemistry, Harvard University, Cambridge, Massachusetts 02138. Received November 17, 1966*

**Abstract:** The mass spectra of guanine, its 1-, 3-, and 7-methyl derivatives, and of isocytosine, hypoxanthine, adenine, and 6-methylaminopurine have been analyzed with the aid of high-resolution mass measurements, metastable peaks, and deuterium labeling. The major electron-impact fragmentation pattern exhibited by guanine and its mono-N-methyl derivatives consists of initial expulsion of a cyanamide fragment, which contains N-1, C-2, and the amino nitrogen atom, followed by decarbonylation. This sequence thus involves all the guanine atoms which take part in the Watson-Crick pattern of hydrogen bonding in polynucleotides. In contrast, the initial fragment expelled from the adenine molecular ion originates uniquely from a single site only when the amino group is methylated.

**G**uanine (2-amino-6-oxypurine; the prevailing 1H tautomer is shown as 1) and adenine (6-amino-purine, 2) comprise the major purine components of

both ribo- and deoxyribonucleic acids, and of a variety of coenzymes and biosynthetic intermediates as well.<sup>2</sup> Most of the minor purine constituents of both transfer RNA<sup>3,4</sup> and of DNA<sup>5</sup> consist of mono- and dimethyl derivatives of 1 and 2.

It has recently been demonstrated that adenine also is the principal component of a number of alkaloids, including the cytokinins, which under certain conditions are powerful stimulators of plant cell division. The naturally occurring compounds in this series include zeatin, 6-(4-hydroxy-3-methyl-2-butenyl)aminopurine, isolated as the free base<sup>6</sup> and possibly as a nucleoside and nucleotide<sup>7</sup> from maize, and its deoxy derivative,

6-(3-methyl-2-butenyl)aminopurine.<sup>8,9</sup> The latter compound has been isolated both from a bacterium<sup>10</sup> and, in the form of its ribonucleoside, as a minor component of transfer RNA in yeast<sup>8,11</sup> and in calf liver.<sup>8</sup> The isomeric 6-amino-3-(3-methyl-2-butenyl)purine, which is devoid of cytokinin activity, has been identified as the alkaloid triacanthine.<sup>12</sup>

Mass spectrometry played a significant but limited role in the elucidation of the structures of these substituted adenine derivatives, and has also been applied in studies of the mechanism of biological methylation of transfer RNA,<sup>13</sup> but to date no systematic study of the mass spectra of the parent compounds has been published. The mass spectra of purine nucleosides, in which the fragmentation patterns of the purine moieties have received relatively little attention, have been used in studies both of nucleic acid components<sup>13,14</sup> and of certain antibiotics.<sup>15,16</sup> We present here the mass spectra of guanine, adenine, and some of

their derivatives, in which the fragmentation patterns have been characterized by metastable peaks and by high-resolution mass measurements of fragment ions. We have sought especially to identify fragments which originate characteristically and uniquely from specific atomic groupings within these molecules, and, where possible, to suggest reasonable structures and mechanisms for the formation of fragment ions.

### Experimental Section

The compounds studied were commercial preparations of the highest purity available, and were obtained from the California Corporation for Biochemical Research, Schwarz BioResearch Inc., Cyclo Chemical Corp., K and K Laboratories Inc., or Aldrich Chemical Co. All preparations were checked for chromatographic homogeneity on paper prior to use. 3-Methylguanine (Cyclo) contained a trace of yellow contaminant, apparently quite polar from its chromatographic behavior, which could be removed by recrystallization from water and which did not contribute significant "noise" to the spectrum of the much more volatile purine. A more polar, ultraviolet-absorbing impurity, identified by  $R_f$  values and by infrared spectroscopy as guanine, invariably contaminated samples of 1-methylguanine, and was found in amounts ranging from a trace to more than 90% of the mixture. Preparations containing only traces of guanine provided intense spectra of the more volatile 1-methyl derivative which displayed no significant peak at  $m/e$  151, the molecular ion and base peak in the spectrum of guanine, and were used without purification.

Readily exchangeable protons (amino, imidazole, "hydroxy") were replaced with deuterium by warming briefly (*ca.* 15 min) in neutral or basic  $D_2O$  and then rotary evaporating the neutralized solution to dryness. If necessary, the procedure was repeated until the expected number of deuterium atoms had been incorporated. Prolonged refluxing (*ca.* 1 hr) in  $D_2O$  effects replacement of an additional proton by deuterium. This has been shown to occur at C-8 in purine,<sup>17</sup> and is presumed to occur at this position in substituted purines as well. The reaction seems to be general for imidazole derivatives,<sup>18,19</sup> and occurs readily in caffeine (3), where the reaction

can be followed unambiguously by pmr spectroscopy.<sup>18</sup> In the cases of adenine and hypoxanthine (6-oxypurine; the 1H tautomer is illustrated as 4), where the magnetic resonance signals of the C-2 and C-8 protons are very close together and are both pH and concentration dependent, only one peak decreases steadily in intensity and finally disappears as deuteration proceeds. Thus hypoxanthine (mol wt 136) readily exchanges two protons for deuterium, forming 1,7(9)-dideuteriohypoxanthine (hypoxanthine- $d_2$ ,

mol wt 138), which on prolonged refluxing slowly exchanges a third hydrogen atom to yield 1,7(9),8-trideuteriohypoxanthine (hypoxanthine- $d_3$ , mol wt 139). Adenine behaves similarly.

Mass spectra were obtained with an Associated Electrical Industries (Ltd.) MS-9 double-focussing mass spectrometer, using a direct-insertion probe. The voltage of the electron beam was occasionally lowered from the standard 70 ev to 30, 20, or 16 ev to suppress high-energy fragmentation paths and to increase the intensity of metastable peaks. Standards for high-resolution mass measurements included argon, nitrogen, and fragments of perfluorotri-*n*-butylamine.

### Results and Discussion

The most intense peak in the mass spectra of guanine and its 1-, 3-, and 7-methyl derivatives is that of the molecular ion, from which a variety of fragments are expelled to produce three groups of primary fragment peaks of weak (less than 10%) to moderate (less than 40%) relative intensity. These occur at  $M - (16-17)$ , due to loss of the amino group or ammonia; at  $M - (41-42)$  or, in the case of 1-methylguanine, at  $M - (55-56)$ , resulting from expulsion of cyanamide fragments; and in some cases at  $M - (27-30)$  due to ejection of carbonyl and methylamine fragments. The initial expulsion of a neutral cyanamide fragment is the predominant and most characteristic mode of decomposition of a guanine molecular ion, and is followed by a well-defined sequence of subsequent fragmentation steps which give rise to the major peaks in the mass spectra of these compounds. The cyanamide fragments originate uniquely from N-1, C-2, and the amino group in the pyrimidine ring of guanine, a conclusion which follows from comparison of the mass spectra of its N-methyl derivatives.

The mass spectrum of 3-methylguanine (Figure 1) is characterized by fragment ion peaks at  $m/e$  123, 95,

2. Fragmentation paths of 3-methylguanine. The  $m/e$  values of observed metastable peaks are given to 0.1 mass unit, together with the transitions to which they have been assigned. Dashed lines designate transitions for which metastable peaks were not observed, but which reasonably account for the presence in the  $m$  of the indicated peaks. Heavy arrows indicate the primary fragmentation processes. The elemental compositions of all fragments indicated in this and other fragmentation diagrams were established by high-resolution mass measurements.

and 41, whose sequential formation from the molecular ion at  $m/e$  165 is well documented by the presence of metastable peaks (Figure 2). Mechanisms for some of these fragmentation processes are proposed in Scheme I.<sup>30</sup> Expulsion of cyanamide from the mo-

The conjugated  $\pi$ -electron systems of the molecular ion and unpaired fragment ions can accommodate delocalization of the posi-

Figure 3. Mass spectrum of 1-methylguanine at 70 eV.

lecular ion, 5, is readily explained by a retro Diels-Alder mechanism which results in the formation of ion 6 at  $m/e$  123. Decarbonylation is the only significant fragmentation reaction of ions having the elemental composition of 6; a metastable peak at  $m/e$  75.0 ( $123 \rightarrow 96$ ) for the loss of  $HCN$  is too weak to be considered unequivocal. The decarbonylation product at  $m/e$  95, ion 7, loses  $HCN$  followed by either the methyl group or another molecule of  $HCN$ . While 7 is a likely candidate for rearrangement, and could give rise to highly stabilized heteroaromatic ions such as 8 by redistributing its methyl hydrogen atoms within an expanded ring, the methyl group remains intact in a substantial fraction of these ions. The fragmentation of 7, therefore, probably proceeds by several paths, among them the sequence indicated.

The ions at  $m/e$  122 and 124 may derive partly from the molecular ion, but this interpretation is not supported by the presence of metastable peaks. The  $m/e$  122 ion is probably formed primarily by expulsion of a hydrogen atom from 6, chiefly from the methyl group. Except for the  $^{13}C$ -containing fragment at  $m/e$  124, these are even-electron ions, and although they follow basically the fragmentation sequence outlined in Scheme I, their fragments at  $m/e$  67 and 69 show no tendency to eject a methyl radical: the peak at  $m/e$  54 is small and that at  $m/e$  52 is negligible. The molecular ion can also lose  $HCN$  and, by processes involving hydrogen rearrangements,  $H_2CN$  (not  $CO$ !),  $HCO$ , or  $NH_3$ . However, the resulting peaks at  $m/e$  136–138 and at 148 are very small, as are the secondary fragmentation peaks which appear in clusters at intervals of approximately 27 mass units below the group at  $m/e$  136–138.

The location of the methyl group in 1-methylguanine has several important consequences for the electron-impact fragmentation patterns of this molecule. First, the methyl group is always lost with the cyanamide fragments, as a result of which peaks are observed at  $m/e$  110 and 109 (i.e., at  $M - 55$  and  $M - 56$  in Figure 3). Neutral methylcyanamide fragments expelled from the molecular ion retain three or four of the five hydrogen atoms originally associated with the amino and methyl groups. When all five are retained, i.e., when hydrogen rearrangement does not accompany frag-

ment, the positive charge (and the unpaired electron in ion radicals) over all the atoms of second-row elements present except (perhaps) methyl carbon atoms. It is often extremely difficult adequately to represent the structures of such ions, especially when they contain many heteroatoms whose "lone pair" electrons in fact contribute to the  $\pi$ -electron population. In attempting to understand fragmentation patterns it is frequently more instructive to consider a single valence-bond structure for a given ion, rather than the resonance hybrid to which it contributes. We have freely adopted this approach in Scheme I and elsewhere in this paper.

Figure 4. Electron-impact fragmentation reactions of the 1-methyl-guanine molecular ion.

Figure 5. Mass spectrum of guanine at 70 eV.

mentation, the methylcyanamide fragment also retains the charge, and gives rise to the major component of the peak at  $m/e$  57. As expected, loss of neutral cyanamide fragments is followed by decarbonylation and subsequent loss of HCN. There are no significant peaks at  $M - 41$  and  $M - 42$ , which indicates that N-1 is always the sole nuclear nitrogen atom lost when cyanamide fragments are expelled from guanine derivatives. This generalization applies even when, as in the present case, the arrangement of double bonds in the pyrimidine ring interferes with the mechanism presented in Scheme I for this reaction. This interference is a second consequence of the location of the methyl group at N-1, and results in lower relative intensities for the ions produced in the series of reactions initiated by expulsion of a cyanamide fragment (compare peaks at  $m/e$  123, 95, and 68 in Figure 1 with corresponding peaks at  $m/e$  109–110, 81–82, and 54–55 in Figure 3). The presence of the methyl group at N-1 also tends to stabilize the positive charge in that region of the guanine molecule. The stabilization of charge, together with the decreased occurrence of competing processes, results in an increased tendency for cleavage of the "single" bonds in the molecular ion in the vicinity of N-1, as indicated by the increased intensity of peaks at  $m/e$  135–137 (loss of carbonyl or methylamine fragments). Some of these fragments can also be lost simultaneously, producing the major component of the  $m/e$  109 peak and all of the  $m/e$  108 ions (Figure 4).

The mass spectrum of guanine (Figure 5) is essentially identical with that of 1-methylguanine below  $m/e$  120, with the exception that peaks at  $m/e$  43 and 44, due to  $\text{CH}_3\text{N}_2^+$  and  $\text{CH}_4\text{N}_2^+$  (cyanamide) ions originating at

Figure 6. Major electron-impact fragmentation reactions of the guanine molecular ion.

least in part from the molecular ion, replace the corresponding  $m/e$  57 peak in the spectrum of 1-methylguanine. Decarbonylation is not a significant decomposition reaction for the guanine molecular ion in the absence of a methyl group at N-1. Deamination (followed by decarbonylation) and expulsion of HNCN are the only major fragmentation processes which compete with loss of cyanamide (Figure 6). The ions at  $m/e$  109–110 produced by the latter reaction eject CO and HCN, preferably but not exclusively in the order given, producing the peaks at  $m/e$  81–83 and 54–55; these processes are not completely defined by metastable peaks. The ability of guanine to lose cyanamide fragments containing one or two hydrogen atoms, the loss of fragments other than cyanamide from the molecular ion, and the over-all low intensity of fragment ion peaks resemble the characteristics of 1-methylguanine, rather than those of 3-methylguanine. This suggests that the prevailing tautomer of guanine in the vapor phase is the linearly conjugated structure 1 in which the pyrimidine ring proton resides on N-1; this is, of course, the familiar tautomer encountered in aqueous solutions and in polynucleotides.

The mass spectrum of 7-methylguanine (Figure 7) is more plentifully endowed with metastable peaks than the spectrum of guanine. A more complete analysis of the fragmentation paths is therefore possible (Figure 8), but the major features of the spectra of the two compounds are quite similar. The 7-methylguanine molecular ion undergoes deamination and loss of cyanamide fragments, but reactions involving expulsion of CO, HCO, or methylamine fragments are extremely minor processes in sharp contrast to the behavior of the 1-methyl isomer. Ejection of an isocyanate fragment from the molecular ion also does not occur to any significant extent, although this reaction is undergone both by the 1-methyl isomer and by guanine itself. The major fragmentation path consists of ejection of cyanamide fragments, giving rise to the peaks at  $m/e$  123 and 124, after which much of the fragmentation pattern is analogous to that of 3-methylguanine with respect to the  $m/e$  values, but not the relative intensities, of successive fragmentation peaks (compare Figures 2 and 8). It is noteworthy that ion 9 at  $m/e$  95, the unrearranged product of successive loss of cyanamide and CO from the 7-methylguanine molecular ion, differs from the corresponding daughter ion of 3-methylguanine (7) only in the position of the methyl group, which in 9 is poorly situated to participate in

Figure 7. Mass spectrum of 7-methylguanine at 70 eV.

Figure 8. Fragmentation paths of 7-methylguanine.

ring expansion to structures such as 8. This may explain why the  $m/e$  95 peak is prominent in Figure 1 but very weak in Figure 7, while the  $m/e$  68 peak which results from loss of HCN from the  $m/e$  95 ions is prominent in both.

The combined presence of the amino group at C-2 and the keto function at C-6 in guanine and its mono-methyl derivatives serves to limit the fragmentation reactions of the molecular ion to the pyrimidine ring. The mass spectrum (Figure 9) of 2-amino-4-oxypyrimidine (isocytosine), whose arrangement of functional groups corresponds to that of guanine, is qualitatively quite similar to the high-mass region of the spectrum of the latter. Analysis of metastable peaks, together with high-resolution mass measurement of fragment ions (Figure 10), confirms that the same neutral fragments and the  $CH_2NH_2^+$  ion are expelled from the molecular ions of both compounds. However, it is apparent from Figure 9 that loss of CO from the molecular ion is a far more important process for isocytosine than it is for guanine or any of the mono-N-methyl-

Figure 9. Mass spectra of isocytosine at 70 and 20 eV.

guanines, and that fragmentation in general is much more facile for the pyrimidine ion. It follows that the aromatic imidazole ring fused to the isocytosine molecule in guanine derivatives stabilizes the molecular ion by delocalizing the positive charge and thus depresses the tendency toward fragmentation, but does not otherwise alter the modes of decomposition of the molecular ion. This stabilization is least effective when the arrangement of bonds in the pyrimidine ring allows the molecular ion to undergo a facile retro Diels-Alder reaction, as in the case of 3-methylguanine, or of 2,6-dioxypurines (xanthines).<sup>21</sup>

Purines which contain only one functional group in the pyrimidine ring show a much less pronounced tendency for one fragmentation reaction of the molecular ion to predominate over all the others. Omission of the amino group from the guanine molecule yields hypoxanthine (4), whose mass spectrum (Figure 11) is notable for the extremely low intensities of its fragment

(21) G. Spiteller and M. Spiteller-Friedmann, *Monatsh. Chem.*, 93, 632 (1962); J. M. Rice and G. O. Dudek, in preparation.

Figure 10. Major fragmentation paths of isocytosine. The distribution of fragment ions suggests that the 3H tautomer of isocytosine (shown) predominates in the vapor phase.

Figure 11. Mass spectrum of hypoxanthine at 70 ev.

Figure 12. Fragmentation paths of hypoxanthine. The existence of multiple fragmentation reactions for the molecular ion suggests that the 1H tautomer predominates in the vapor phase.

ion peaks. This spectrum suggests, however, that the major determinant of the guanine fragmentation pattern is the carbonyl function and not the amino groups, for to a large extent hypoxanthine expels neutral fragments

Figure 13. Mass spectrum of adenine at 70 ev.

Figure 14. Principal fragmentation paths of adenine.

from the same sites and in the same order as guanine. The molecular ion can eject a hydrogen atom, CO, or HCN, but the preferred process is expulsion of HCN, followed by CO and another molecule of HCN (Figure 12). The  $M - 27$  peak persists with *undiminished relative intensity* in the mass spectra of hypoxanthine- $d_1$  and hypoxanthine- $d_2$ , and loss of HCN from the latter must include C-2. The initial loss of HCN from the hypoxanthine molecular ion thus corresponds principally to the expulsion of cyanamide fragments by guanine, and is inferred to involve N-1 as well as C-2. The subsequent decarbonylation and loss of HCN represent a continuation of the guanine fragmentation pattern. Expulsion of a charged cyanamide fragment from guanine also finds an analogy in the formation of  $H_2CN^+$  from hypoxanthine, but not all of the protonated HCN fragments which originate from the molecular ion do so from the same site as the neutral HCN discussed above. The  $m/e$  28 peak due to  $H_2CN^+$  shifts cleanly to  $m/e$  29 ( $HDCN^+$ ) in the spectrum of hypoxanthine- $d_2$ , but its total intensity is divided nearly equally between peaks at  $m/e$  29 and 30 ( $D_2CN^+$ ) in the spectrum of hypoxanthine- $d_3$ . A metastable peak in the latter spectrum at  $m/e$  6.5 ( $139 \rightarrow 30$ ) confirms the origin of some of the  $D_2CN^+$  ions from the molecular ion, and therefore from the imidazole ring.

If the carbonyl group of hypoxanthine and its associated proton are replaced by an amino group, the neutral fragments expelled from the resulting adenine

The multiple origins of cyanide molecules produced at each stage of fragmentation in adenine- $d_2$  and adenine- $d_4$ .

ar ion no longer show any tendency to originate from a single site. The mass spectrum of (2; Figure 13) is characterized chiefly by fragment peaks at  $m/e$  108, 81, and 54 due to successive loss of three molecules of HCN, although other ions are occasionally lost along the way (Figure 15), proving that many fragmentation paths contribute to the mass spectrum. Similar behavior of the unsubstituted purine molecule recently been analyzed in detail.<sup>23</sup>

Loss of the amino group from the molecular ion is an only minor process for adenine, but if the amino group is methyl substituted, the initial fragments lost from the molecular ion originate predominately from the methylamino group. 6-Methylaminopurine (Figure 16) preferentially expels 28 or 29 mass units ( $\text{CH}_2\text{N}$  or  $\text{CH}_3$ ) from the molecular ion. This process consists of the methylamino group with concomitant loss of one or two hydrogen atoms to the purine ring, followed in each case by successive loss of molecules of HCN. A high-energy variant, not at 16 eV, involves initial loss of a hydrogen atom from the remaining 29 mass units of the methylamino group. When the entire methylamino group is lost as a single unit, it retains the positive charge, resulting in the  $\text{CH}_4\text{N}^+$  ion at  $m/e$  30. Methylation of the amino group thus introduces a powerful and unifying influence into the chaotic array of fragmentation patterns which otherwise characterize the adenine molecule.

#### Ions

The characteristics of guanine appear to be much more favorable than those of adenine or hypoxanthine

Tatematsu, T. Goto, and S. Matsuura, *Nippon Kagaku Zasshi*, 86.

Figure 16. Mass spectra of 6-methylaminopurine at 70 and 16 eV.

for obtaining unambiguous structural information from the mass spectra of derivatives of these compounds. It is noteworthy that guanine in nucleic acids is much more reactive than adenine toward both mutagens of the mustard type<sup>23</sup> and certain carcinogenic compounds,<sup>24</sup> and the application of mass spectrometry to the study of such reactions should prove fruitful.

# Optical Properties and the Chemical Nature of Acyl-Chymotrypsin Linkages

Elliot Charney and Sidney A. Bernhard

Contribution from the Laboratory of Physical Biology, National Institute of Arthritis and Metabolic Diseases, National Institutes of Health, Bethesda, Maryland, and the Department of Chemistry and Institute of Molecular Biology, Eugene, Oregon. Received November 19, 1966

**Abstract:** On the supposition that the specific spectral properties of mono- $\beta$ -arylacryloyl enzymes are related to their special reactivity, the spectra and optical rotatory dispersions of  $\alpha$ -chymotrypsin and some acyl derivatives have been examined and compared with the spectra and optical rotatory dispersions of a group of relevant small molecules. The reactivities of these acyl enzymes have previously been correlated with their catalytic functions in specific substrate reactions, and there are considerable presumptive arguments that the acyl-enzyme linkage is *via* a specific serine hydroxyl oxygen (an ester linkage). The spectral properties, especially the large red shifts on acylation, and chemical reactivities of these mono- $\beta$ -arylacryloyl enzymes differ from those of small molecule model acylserine esters. On the basis of the comparisons of their optical properties, these differences are found to be due to an *endo*-energetic configurational change which takes place when the enzyme is acylated with the  $\beta$ -acryloyl substrates. It is found that the "native"  $\beta$ -acryloyl enzyme has a "*s-cis*" configuration in contrast to the small molecule model compounds which are predominantly in the "*s-trans*" configuration. The magnitude of the induced optical rotatory activity attributable to the transition associated with the absorption band of the  $\beta$ -acryloyl component of the acetylated enzyme, nmr measurements on model compounds, and other spectral information are shown to exclude other possible configurational changes such as out-of-plane skewing or *cis-trans* isomeration about the double bonds. Chemical perturbation (*via* enzyme substituents) of an otherwise conventional acyl-serine linkage is also considered and rejected as an unlikely origin of the observed spectral shifts.

A number of detailed studies of the chemical and spectral properties of aroyl chymotrypsins have been reported.<sup>1-3</sup> These aroyl enzymes can be prepared, virtually stoichiometrically, by reactions of the type illustrated in eq 1. Under appropriate conditions

of pH, when the "leaving group" is strongly electron withdrawing, this specific monoacylation reaction may be sufficiently faster than the succeeding deacylation reaction (eq 2) for the acyl intermediate to be studied in

isolation. A variety of parallels can be drawn between the relatively slow pathways of acylation and deacylation exhibited with these aroyl acylating agents and the rapid turnover of specific substrates (I) of  $\alpha$ -chymotrypsin. Although many of the monoaroyl-

chymotrypsin derivatives are sufficiently stable to be studied spectrophotometrically by conventional tech-

niques, they are all nevertheless strikingly more reactive than the corresponding aroylalkyl esters. This comparison is of significance since denaturation of the monoacyl enzyme leads to the formation of an identifiable monoacylserine O-ester peptide.<sup>3-5</sup> The aromatic nature of the acyl-enzyme derivatives reported herein is of no particular chemical catalytic consequence; aliphatic acyl enzymes have similar chemical properties.<sup>6,7</sup> Due to its intense ultraviolet absorption, the aroyl group provides an indicator of the electronic environment at the site of covalent attachment to the enzyme. The effectiveness of this system as an electronic indicator can be greatly enhanced by extension of the  $\pi$ -resonance systems as in derivatives of type II or III because the intense  $\pi$ - $\pi^*$  transition occurs at longer wavelengths and so sufficiently outside the region of ultraviolet absorption of the enzyme to simplify the spectrophotometric measurements. In addition, equally energetic shifts result in larger shifts in wavelength because of the inverse nature of the relationship between energy and wavelength.

Denatured solutions of the mono- $\beta$ -arylacryloyl-enzyme derivatives have similar chemical properties and identical ultraviolet and/or near-visible spectra when compared with model serine peptides containing

responding acyl ester linkage (III).<sup>2,4</sup> On the other hand, the native derivatives have strikingly dif-

ferent chemical and spectral properties. The studies described herein were undertaken as part of an attempt to investigate the relevance of these unusual spectral properties to the chemical catalytic process.

In order to clarify our objective in the present series of experiments, it is well to restate a number of previously noted facts concerning the spectral properties of acyl enzymes of type II in the native and in the denatured (or degraded) state.

The strong long-wavelength electronic transition of the acyl chromophore is always "red shifted" in the native acyl enzyme, relative to the denatured enzyme;<sup>2</sup> the red derivatives are *always* identical in spectrum with model O-acylserine-peptide derivatives and with electrolytically degraded O-acylseryl-enzyme fragments.<sup>1,3</sup>

The same strong long-wavelength electronic transition in the native acyl-enzyme derivative is always comparable in intensity to that of the denatured or compound derivatives.

This spectral "red shift" which varies considerably from derivative to derivative ( $\Delta\lambda$  can be as large as 100 mμ) is unexpected in view of the finding that this native enzyme binding site resembles an environment of low polarity (a "hydrophobic" binding site); acyl chromophores thus far considered are "blue shifted" when transferred to solvents of low polarity. Alternatives have been previously proposed to exclude the possibility that the red shift arises from a difference in solvent polarity" surrounding the chromophore in the native *vs.* the denatured (unfolded) acyl enzyme.<sup>8</sup>

All experimental measurements of the kinetics of denaturation, enzyme inactivation, and disappearance of the red shift in the acyl chromophore have failed to indicate any "uncoupling" in the three processes (kinetics of the three processes are identical). The implication is that this red shift is a relevant property of the catalytic process.

Alternative explanations for the red shift have been previously proposed,<sup>1,3</sup> but no clear-cut choice is

made in recent studies<sup>9</sup> with somewhat conflicting results are most significant in this respect. One by Kallos and Avatis would further emphasize the special requirement for explaining the red shift of the native derivatives since these authors have demonstrated from studies of model derivatives that the solvent-dependent blue shift observed when an active site is bound to the active site of the enzyme is directly related to the polarity of the binding site. In the other, Westheimer, *et al.*, the photolysis products of diazoacetyl-chymotrypsin and the active site water is present at the active site. If the latter result requires that the active site has a polar environment, then no special requirement for a spectral shift large enough to overcome the solvent effect. Kallos and K. Avatis, *Biochemistry*, 5, 1979 (1966); J. Shafer, J. Lowsky, R. Laursen, F. Finn, and F. H. Westheimer, *J. Biol. Chem.*, 241, 421 (1966). Figure 1. Potential mechanisms for the perturbation of the  $\beta$ -acryloyl-enzyme spectra: E = enzyme or peptide. The fact that the acryloyl group is shown linked to the enzyme or peptide before and after the isomerization is not intended to indicate necessarily that the isomerizations or out-of-plane rotations take place after acylation. The arrows are intended to indicate out-of-plane bending which for angles less than  $180^\circ$  results in skewed configurations.

evident from the existing experimental data. The alternatives previously proposed are as follows.

(1) The acyl enzyme is a "chemically perturbed" serine ester, the perturbation being of a type thus far not observed in model compound esters of this type.

(2) The native acyl-enzyme linkage is not *via* a serine O-ester linkage, but rather *via* an *active* acyl linkage which is transferred to the hydroxyl oxygen of serine upon denaturation of the acyl enzyme.

Extensive investigations of the denaturation process, under a variety of conditions of pH, have thus far demonstrated the invariant coupling of the red-shift disappearance to the denaturation process, and hence led us to reject as unlikely (although not impossible) the second of these alternatives. We chose, therefore, to consider the detailed electronic and stereochemical possibilities consistent with the former alternative. Three straightforward mechanisms for perturbing the spectra of esters of type III can be summarized as follows: (1) *cis-trans* isomerizations or "out-of-plane" rotations about the  $\alpha,\beta$  double bond; (2) *s-trans-s-cis* isomerizations or rotation about the acryloyl carbon-carbon single bonds; (3) interactions with electrophiles at either carbonyl oxygen or interactions with nucleophiles at the carbonyl carbon *via* the constituent amino acid residues of the enzyme protein or *via* solvent. These mechanisms are summarized in Figure 1.

The present experiments are designed to explore the first two possibilities. Experimental data of two types

have been obtained from spectroscopic and optical rotatory dispersion studies of both model arylacryloyl compounds and of related acyl enzymes.

## Experimental Section

**Model Compounds and Reagents.** Cinnamic acid,  $\beta$ -(2-furyl)acrylic acid, methyl cinnamate, and ethyl  $\beta$ -(2-furyl)acrylate were purified commercial samples previously described.<sup>3</sup>  $\beta$ -(2-Furyl)acrolein and  $\alpha$ -methyl- $\beta$ -(2-furyl)acrolein were obtained from K. & K. Chemical Co. The former was recrystallized from water and the latter redistilled under reduced pressure.  $\alpha$ -Methylcinnamic acid (Aldrich Chemical Co.) was recrystallized from water and dried under vacuum. N-[ $\beta$ -(2-Furyl)acryloyl]imidazole was prepared as previously described.

N-Carbobenzoyloxy-O-furylacryloyl-L-serinamide was prepared from a recrystallized sample of N-carbobenzoyloxy-L-serinamide, the optical purity of which has been established; 0.01 mole of the amide was dissolved in 20 ml of cold (5°) pyridine and 0.01 mole of  $\beta$ -(2-furyl)acryloyl chloride<sup>3</sup> in 10 ml of tetrahydrofuran was slowly added. Solvent was removed after 5 min by flash evaporation at room temperature. The resultant gum was extracted with ethyl acetate, and the ethyl acetate solution was extracted exhaustively with aqueous phosphate buffer (0.5 M, pH 6.7). The ethyl acetate layer was then dried over  $\text{Na}_2\text{SO}_4$ , filtered, and made slightly turbid by the addition of Skellysolve B. On standing at 5° crystals formed. These were filtered, air dried, dissolved in 95% ethanol, recrystallized from hot ethanol-H<sub>2</sub>O (~50% v/v), and dried in a vacuum oven at 40°; mp 158–160°; equiv of serine/358 g of product, 0.98;  $\epsilon_M$   $2.6 \times 10^4$  (OD/M cm) at 303 m $\mu$ .

$\beta$ -(2-Furyl)acryloyl- $\alpha$ -chymotrypsin was prepared by the stoichiometric reaction of  $\alpha$ -chymotrypsin with the acylimidazole as described previously.<sup>3</sup> The method involved the addition of microliter quantities of the acylimidazole to milliliter quantities of enzyme solution. It was therefore possible to measure spectra and optical properties of the enzyme solution before and after acylation, without transfer of sample from one cell to another. Denatured enzyme and denatured acyl enzyme were prepared in soluble form by the addition of concentrated (0.1 M) solutions of sodium dodecyl sulfate (to a final concentration of about 0.02 M).

Spectrograde organic solvents (Matheson Coleman and Bell Chemical Co.) were utilized throughout.

**Spectrophotometric and Optical Rotatory Dispersion Measurements.** All spectrophotometric studies were carried out in a Cary Model 14 spectrophotometer. Maximal slit widths were approximately 0.2 mm. Optical rotatory dispersion measurements were performed with the aid of a Cary Model 60 spectropolarimeter at spectral band widths of 20 Å or less. Cylindrical quartz cells could be used interchangeably in the two instruments. Unless otherwise noted, optical densities in the polarimetric experiments did not exceed 1.0 OD. Depending on the stability of samples, the spectra of polarimetric samples were determined either concurrently (with aliquots of the same solutions) or by direct measurements in the polarimetric sample cells, after the polarimetric measurements were completed. The kinetics of deacylation of the acyl enzyme was measured spectrophotometrically as previously described.<sup>1,4</sup> Changes in polarimetric properties associated with deacylation were measured both at fixed wavelengths as a function of time and by repeated scanning of the wavelength region at regular intervals in the spectropolarimeter. All spectrophotometric measurements were made at 25° except for the kinetic studies which were run at 27°. Spectropolarimetric studies were all at 27°.

## Results and Discussion

The spectral absorption and optical rotatory dispersion measurements were designed to explore two suggested origins of the red shift of acyl derivatives of the native enzyme. The spectral characteristics of a variety of  $\beta$ -acryloyl derivatives are summarized in Table I. These compounds have been selected with regard to the relevance of their chemical and electronic structure to these spectral shifts. The choice of the furylacryloyl and cinnamoyl derivatives is dictated by the steric and spectral characteristics which make them not only suitable substrates for the enzyme but, as noted earlier, peculiarly sensitive indicators of the chemical and physical effects of their environment.

We will consider first the possibility that the red shift results from "out-of-plane" bending about the  $\alpha,\beta$  double bond or from *cis-trans* isomerization with respect to this bond and show from ultraviolet spectral data, nmr measurements, and measurements of induced optical activity that these mechanisms cannot be the origin of the red shift.

**A. "Out-of-Plane" Bending about the  $\alpha,\beta$  Double Bond.** To demonstrate the effect of out-of-plane bending as a factor in the observed spectral shifts, we chose to examine the substituted derivatives  $\alpha$ -methylfurylacrolein (1) and  $\alpha$ -methylcinnamic acid (3) relative to their unsubstituted homologs furylacrolein (2) and cinnamic acid (4). The former two compounds would be expected to be skewed into a nonplanar (with respect to the conjugated system) configuration because of the effect of  $\alpha$ -methyl substitution on the van der Waal's contacts (Figure 2). Note that in both cases the  $\alpha$ -methyl carbon-*ortho* carbon (or oxygen) contact distance is about 2.5 Å in the planar conformation. Nonbonded C-C contacts this short have never to our knowledge been observed in crystals. The ultraviolet spectra of these compounds (Figure 3) must be examined for perturbing effects other than the known red shift that occurs on  $\alpha$ -methyl substitution (see, for example,

the spectral effect of  $\alpha$ -methyl substitution in acrolein (5, 6) and methacrylic acid (7, 8 and 9, 10—Table I). Note that, instead of the red shift, there is a large blue shift of  $\lambda_{\max}$  in  $\alpha$ -methylcinnamic acid derivatives and a lack of a red shift in the furoyl derivative. The effect is more pronounced in  $\alpha$ -methylcinnamic acid, presumably due to the more unfavorable contacts with two  $\alpha$ -carbons in the phenyl derivative relative to one carbon and one oxygen in the furyl case. It is clear that a large twist out of planarity about the double bond, as must occur in the two  $\alpha$ -methyl derivatives,<sup>10</sup> is inconsistent with the observed spectra of the acyl enzymes. The enzyme derivatives of type II show no large decrease in extinction. More important, the shift in  $\lambda_{\max}$  for the native acyl enzyme is in the wrong direction. In fact, the blue shift in  $\lambda_{\max}$  due to out-

(10) As noted above, examination of space-filling models<sup>11</sup> of  $\alpha$ -methylcinnamic acid indicated that the acrylic group would not maintain a planar configuration. This is in accord with the observed blue shift relative to cinnamic acid. To check this, we examined the nmr chemical shift of  $\alpha$ -methylcinnamic acid relative to  $\alpha$ -methylacrylic acid. On the basis of the coordinates taken from the models and the theory of the effect of aromatic ring currents on nmr chemical shifts (C. E. Johnson and F. E. Bovey, *J. Chem. Phys.*, 29, 1012 (1958)), the  $\alpha$ -methyl protons in the cinnamic acid derivative are expected to be 31 cps downfield with respect to those of the acrylic acid derivatives if the entire conjugated system is planar and *upfield* by about 5 cps if the system is skewed about 90° out of plane. The experimentally observed shift is 11 cps *upfield*, in excellent confirmation of the ultraviolet interpretation of nonplanarity. We wish to thank Mr. Robert Bradley of the National Institutes of Health for making these measurements.

(11) Pauling, Corey, and Koltun models developed by the Atomic Models Subcommittee of the Biophysics and Biophysical Chemistry Study Section of the National Institutes of Health.

of-plane distortion is undoubtedly even greater than that observed since, as we have seen, the  $\alpha$ -methyl group contributes electronically (*ca.* 10 m $\mu$ ) to an increase in  $\lambda_{\max}$  over the homologous  $\alpha$ -hydrogen derivative

Figure 2.  $\alpha$ -Methyl-*trans*-cinnamic acid drawn to scale in the planar conformation from Dreiding models, showing the van der Waals overlap of hydrogen atoms on the aromatic ring with those on the methyl group. Two of the three methyl hydrogens are eclipsed with respect to the plane of the ring. van der Waals radius of hydrogen = 1.00 Å.

(see Table I). The effects of out-of-plane twisting in skewed dienes have been very extensively investigated in regard to the effect of skew on both the ultraviolet spectra<sup>12,13</sup> and the optical rotatory dispersion.<sup>14</sup>

All spectra were taken in 1-cm cells; solvent  $CH_2Cl_2$ .

Figure 4. Optical absorption and rotatory activity of nonplanar conjugated dienes calculated from Hückel molecular orbitals. (a) Dependence on skew angle of the long-wavelength  $\pi \rightarrow \pi^*$  transition of a conjugated diene. (b) Dependence on the skew angle of the rotational strength of the long-wavelength  $\pi \rightarrow \pi^*$  transition of a conjugated diene (positive rotational strength corresponding to right-handed helical configuration, only, is shown).

Although a large out-of-plane skew can be ruled out solely on the basis of the foregoing considerations

Figure 5. Induced molar rotation  $[\Delta M] = [M](FAI + \alpha$ -chymotrypsin)  $- [M](\alpha$ -chymotrypsin)] of acetylated enzyme complex on native enzyme at pH 4.30,  $27^\circ$ ; (FAI) 0.0142 mg/ml; ( $\alpha$ -chymotrypsin) 2.61 mg/ml. Insert: absorption spectrum 3 min after addition of FAI.

and of the observed spectra of native acyl enzymes, smaller skew angles cannot be summarily dismissed on this basis. In the case of small angles, however, the recent interpretation of the ultraviolet spectra<sup>12,13</sup> and the optical rotatory dispersion<sup>14</sup> of skewed conjugated systems offers some help. The effect of skew angle on  $\lambda_{max}$  is shown schematically in Figure 4a. For small skew angles a blue shift is predicted, but the shift is small enough so that structural environmental effects may have stronger influences on the position of maximum absorption. The possibility of out-of-plane skew of the chromophoric group in the native acyl enzyme can, however, be tested more quantitatively by comparing the observed optical activity with that predicted from theoretical considerations. Rotational strength is expected to be very similar to that calculated for skew dienes (Figure 4b). It is easy to see that, although only small spectral shifts are expected, the rotational strength undergoes a large change even for small angles. The optical rotatory dispersion of  $\alpha$ -chymotrypsin and  $\beta$ -(2-furyl)acryloyl- $\alpha$ -chymotrypsin in native and denatured (sodium dodecyl sulfate) states was therefore measured. A notable difference was observed between the native enzyme and the native acyl enzyme (Figure 5). Note that this difference in rotatory dispersion disappears when the enzymes are denatured (Table II). The "Cotton effect" induced by furylacryloylation corresponds approximately in wavelength to that predicted on the basis of the measured absorption band due to the furylacryloyl chromophore of the native enzyme (Figure 5, insert). The induced rotatory

## Optical Activity of Acyl Complexes

ations measured at 3350 Å, the peak of induced activity in II, the native acyl-enzyme complex. The activity of solution was measured 3 min after the addition of the acryloyl complex.

In a separate experiment at pH 6.24 the maximum induced was found to be from 20 to 25% higher than that obtained in I and II were measured at pH 4.30, III and IV at pH 7.0. Measured on the Cary 60 spectropolarimeter at the University of Oregon, for which we wish to thank Professor John Schell. Measured on the Cary 60 spectropolarimeter at the National Institutes of Health.

tion is related to the catalytic site configuration indicated by the fact that this induced rotatory activity disappears with time (Figure 5), presumably a process related to the deacylation of the acyl enzyme (and regeneration of the native enzyme).<sup>15</sup> Additional evidence for this comes from the measurement of the optical activity of the same chromophore bound to a model serine peptide, N-carbobenzoyloxycarbonyl-L-serine. As indicated in Table II, no induced activity within the noise limited detectability of the instrument (approximately  $\pm 0.0004^\circ$  under the conditions of measurement) is observed. Induced effects of the type observed with the native acyl enzyme can have two origins. (a) The chromophoric group itself remains planar, i.e., the nuclear positions are essentially planar configuration but the charge distribution is distorted by the asymmetric environment of the enzyme to give rise to induced optical activity in the positions of the chromophore. This effect will likely be very much smaller than the second type. (b) The chromophoric group itself skews into a non-planar configuration. It is this type which gives rise to optical activity observed in the ultraviolet transition, for example, the steroid dienes.<sup>16</sup> Although there is apparent qualitative consistency between the

should be noted that vicinal dissymmetry is sufficient for optical activity, a condition which is fulfilled when the isolated molecule is bound to a site in fairly rigid orientation (see, for example, D. D. Ulmer, T.-K. Li, and B. L. Vallee, *Proc. Natl. Acad. Sci.* **47**, 1155 (1961), and the results of a recent investigation of mer optical activity by K. Yamaoka and R. Resnik, *J. Phys. Chem.* **70**, 4051 (1966)). Thus it is not a necessity that the optical activity appears even if the helical or otherwise rigidly oriented structure of the protein is destroyed. Nevertheless, it does appear likely that the action of the secondary or tertiary structure is likely to wash out most of the optical activity by increasing the symmetry of the system or destroy it completely by releasing the bound substrate from its rigid orientation. In fact the disappearance of the induced activity, as is the case here, with SDS denaturation of the  $\alpha$ -chymotrypsin, may be used to draw the tentative conclusion that the substrate has been released from its rigid configuration with the denaturation of the protein.

\* Moscovitz, E. Charney, U. Weiss, and H. Ziffer, *J. Am. Chem. Soc.* **83**, 4661 (1961); E. Charney, H. Ziffer, and U. Weiss, *Tetrahedron*, **21**, 1065 (1965); R. Deen and H. Y. C. Jacobs, *Koninkl. Nedl. Akad. Wetenschap. Proc. Ser. C*, **64**, 313 (1961).

observed rotatory dispersion properties and the "skewed double bond hypothesis," the quantitative measure of the "trough" of the "Cotton effect" (Table II) is inconsistent with this hypothesis. Small out-of-plane twists are associated with very much larger troughs in the rotatory dispersion. The magnitude of the expected optical activity may be calculated using the simple approximation that the order of the activity will be that expected from a skew diene (or larger since the conjugated groupings are more extended in the cinnamoyl and furylacryloyl compounds). On this basis it is calculated<sup>14</sup> that the observed optical activity (molar amplitude =  $12 \times 10^3$  degrees/M dm (Table II)) cannot come from configurations skewed more than 3 or 4°, hardly enough to account for significant perturbations in the absorption spectra. We conclude therefore that there is no significant out-of-plane twisting about the  $\alpha,\beta$  double bond in the native acyl enzyme.

**B. Planar *cis-trans* Isomerization about the  $\alpha,\beta$  Double Bond.** This possibility can be eliminated from a consideration of the spectra of model compounds (Table I). For example, the wavelength of maximum absorption of *cis*- and *trans*-methacrylic acids (7, 9) differ by only 0.5 m $\mu$ , and while this is at 205 m $\mu$ , it is still energetically much smaller than the 11-m $\mu$  shifts observed in the cinnamoyl-native enzyme complex (17) (about 120 cm<sup>-1</sup> compared to about 1400 cm<sup>-1</sup> for the latter). The shift to  $\alpha$ -methyl-*cis*-methacrylic acid (10) from the *trans* configuration (8) is accompanied by a small shift of 3 m $\mu$  to the red (somewhat more energetic than the unsubstituted acrylic acid), but, more generally, where the unsaturated system extends over more than two bonds shifts to the blue are encountered. For example, the long-wavelength band of *cis*-stilbene is about 280 m $\mu$  compared to about 295 m $\mu$  for the *trans* compound, and in 1,4-diphenylbutadiene, the conversion from the *trans,trans* configuration to the *cis,trans* is accompanied by a blue shift of about 17 m $\mu$ .<sup>17</sup> The experimental evidence is in full qualitative accord with either simple molecular orbital or free-electron theory,<sup>18</sup> which predicts increasing red shifts with increasing *trans* extension of conjugated systems.

**C. *s-trans-s-cis* Isomerization about the Acryloyl Carbon-Carbon Single Bond.** Spectral data relating to *cis-trans* isomerization of esters of this type are limited. Nevertheless, a number of pertinent studies have been reported.

Referring first to spectral investigations, we note that the methyl ketones 19 and 20, which are known from infrared studies<sup>19</sup> to be respectively in the planar *s-trans* and *s-cis* configuration, have their long-wavelength strong absorption (presumably the  $\pi \rightarrow \pi^*$ ) at 232 and 245 m $\mu$ , respectively, a shift of about 2280 cm<sup>-1</sup> to the red. In the case of the lactones 21 and 22 in which the nominal double bonds are respectively *s-trans* and *s-cis*, the peaks of the same strong absorption band are at 205 and 220 m $\mu$ , a 3230-cm<sup>-1</sup> shift to longer wavelengths,<sup>20</sup> and while a small part of this

(17) J. H. Pinckard, B. Willie, and H. Zechmeister, *J. Am. Chem. Soc.* **70**, 1938 (1948).

(18) See, e.g., the discussion in H. H. Jaffé and M. Orchin, "Theory and Applications of Ultraviolet Spectroscopy," John Wiley and Sons, Inc., New York, N. Y., 1962.

(19) R. L. Erskin and E. S. Wright, *J. Chem. Soc.*, 3425 (1960).

(20) This spectral shift is frequently referred to for configurations of the type of compounds 21 and 22 as due to differences between endocyclic and exocyclic configurations. Without taking up the general

very large change may be due to the hyperconjugative effect of an extra carbon substituent, certainly the major part arises from the relative ground and electronically excited state stabilities of the *s-trans* and *s-cis* configurations.<sup>13</sup>

Studies of the conjugated dienes, both experimentally and theoretically,<sup>21,22</sup> have also shown the *s-trans* → *s-cis* configurational change is accompanied by large red shifts.

One of the most interesting related studies is that of deGroot and Lamb<sup>23</sup> who studied rotational isomers of a number of acrylic molecules by ultrasonic relaxation. Table III summarizes these data on cinnamaldehyde and furoylacrolein. Compare the difference in ground-state energy of these compounds with the data of Bernhard, *et al.*,<sup>3</sup> on the spectral shifts of cinnamoyl and furoyl derivatives upon formation of the acyl enzymes, respectively 1400 and 1140 cm<sup>-1</sup> (309 → 320 mμ and 281 → 292 mμ). The relative energy differences ( $\Delta E_{\text{cinnamoyl}}/\Delta E_{\text{furoylacrolein}}$ ) are 1.23, determined from the spectral shifts, and 1.25, determined from the ultrasonic relaxation studies. The observed red shift is hence consistent with the postulate of *cis-trans* isomerization about the ester single bonds. Moreover, the observed thermodynamic stability of the acyl enzyme<sup>24</sup> is consistent with that expected from a *trans-cis* isomerization between absorbed (*s-trans*) ester substrate and covalent (*s-cis*) acyl enzyme ester.

Table III<sup>a</sup>

	transition state	
	$\Delta H_1 \pm$	$\Delta H_2 \pm$
	<i>s-trans</i>	<i>s-cis</i>
	$\Delta H_0$	
	$\Delta H_1$ , kcal/mole	$\Delta H_0$ , kcal/mole
Cinnamoylaldehyde	5.62	1.5
Furoylacrolein	5.10	1.2

<sup>a</sup> Data from ultrasonic relaxation studies, ref 16.

The hypothesis of *s-trans* → *s-cis* isomerization is supported by two other facts about native acyl enzymes.

questions of this attribution, it should be sufficient to point out that, for this case, the strong perturbation which might be expected from lactone formation is observed to give a much smaller effect than the *s-trans* → *s-cis* (endo → exocyclic) transformation. Thus *s-trans*-β-methacrylic

acid (18) has  $\lambda_{\text{max}}$  205.5 mμ ( $\epsilon$  1.35 × 10<sup>4</sup>) while the *s-trans* lactone 21 has  $\lambda_{\text{max}}$  205 mμ ( $\epsilon$  1.07 × 10<sup>4</sup>).

(23) M. S. deGroot and J. Lamb, *Proc. Roy. Soc. (London)*, **A242**, 36 (1957).

(24) M. L. Bender, G. R. Schonbaum, and B. Zerner, *J. Am. Chem. Soc.*, **84**, 2562 (1962).

(1) Although native acyl enzymes of type II are all significantly red shifted relative to the corresponding alkyl esters (III), acyl enzymes of type IV (in which  $\lambda_{\text{max}}$  and  $\epsilon_{\text{max}}$  are comparable, e.g., benzoyl-, *meta*- and *para*-substituted benzoyl-, and 2-furoylchymotrypsins) are only slightly, or not at all, red shifted.<sup>2</sup> In the latter

acyl enzymes there is either no distinction (benzoyl and *para*-substituted benzoyl) or little distinction (2-furoyl and *meta*-substituted benzoyl) between the *s-cis* and *s-trans* configurations; hence there should be no spectral shift.

(2) Acyl enzymes of type IV are kinetically far more stable toward hydrolysis than are acyl enzymes of type II.<sup>2,24,25</sup> This kinetic stability is not a consequence of electronic contributions ("substituent effects") from the acyl moiety.<sup>26</sup> Acetyl- and cinnamoylchymotrypsins are hydrolyzed at comparable rates. Benzoylchymotrypsin is hydrolyzed nearly two orders of magnitude more slowly. If the native acyl enzyme is always in the *s-cis* configuration so as to allow for attack by water (*i.e.*, if the *s-cis* configuration is of importance in the catalytic pathway), the branched planar  $\beta,\beta',\alpha$  configuration in IV may block the nucleophilic attack

by water. In this regard it is interesting to note the nonplanar (L) configuration at the  $\alpha$ -carbon atom of specific substrates (I) (a requirement for very rapid catalysis), indicative, if the "cis-ester" hypothesis is correct, of a highly critical stereospecificity for nucleophilic attack.

## Conclusions

The spectral investigations reported here support the hypothesis that the acylation of  $\alpha$ -chymotrypsin with acryloyl substrates is accompanied by a *s-trans* to *s-cis* configurational change about the acryloyl single bond. The possibility of chemical perturbation other than structural has not been experimentally examined, but some of the spectral data have a bearing on this ques-

(25) In connection with the mechanism of chymotrypsin activity, T. C. Bruice [*J. Polymer Sci.*, **49**, 101 (1961)] has previously suggested the possible requirement of a *trans-cis* change in the O-ester configuration, similar, and possibly related mechanistically, if not spectroscopically, to the conformational change described here.

(26) S. A. Bernhard, E. Herschberger, and J. Keizer, *Biochemistry*, **5**, 4120 (1966).

tion.<sup>27</sup> If, as seems likely from these results, the endoenergetic configurational change does occur, then any

(27) External chemical modification of the ester linkage: none of the above-mentioned data excludes the possibility of chemical interaction somewhere in the proximity of the ester linkage. From the known properties of esters, aqueous solvent, and amino acid residues of the protein, the plausible loci of chemical interaction are at either of the two ester oxygens or at the carbonyl carbon. Nucleophilic interaction at the (electrophilic) carbonyl carbon can be rejected as a significant contribution, since such attack would effectively decrease the intensity and blue shifts. To a rough approximation, this type of interaction would transform the spectrum of a cinnamoyl derivative to that of a styrene derivative (eq 3). Such an acyl-enzyme derivative would be virtually

unobservable spectroscopically. Electrophilic interaction at oxygen is, however, a distinct possibility. The most obvious electrophilic agent is, of course, a proton (eq 4). Indeed, the spectra of the N-methylamides of cinnamic and furylacrylic acids in strongly acid solutions (approximately 1 M HCL)<sup>28</sup> are red shifted to precisely the same wavelengths as

model of the active site of  $\alpha$ -chymotrypsin must accommodate this requirement.

the corresponding acryloyl enzymes. This result is not unexpected, since protonation of N-methylamides is known to occur at the carbonyl oxygen,<sup>29</sup> a process which would lead to electron delocalization at the C-N bond and hence to a spectrum essentially the same as that observed in the corresponding aldehydes and ketones. The spectra of the protonated furoyl and benzoyl-N-methylamides are similarly red shifted. No such large red shift is observed, however, with the corresponding furoyl and benzoyl enzymes.<sup>3</sup> Moreover, protonation of this type (eq 4) is seemingly unlikely at or near neutrality, where the spectra of the acyl enzymes have been measured. The possibility that hydrogen bonding at carbonyl oxygen, rather than complete proton transfer, is the origin of the red shift cannot be ruled out. No significant red shifts have been noted, however, in the spectra of cinnamoyl and furylacryloyl esters in the presence of very strong hydrogen-bond donors (relative to the corresponding spectra in pure H<sub>2</sub>O).<sup>3</sup>

## The Mechanism of Polymerization of N-Carboxyanhydrides in Dimethylformamide. Evidence of the Presence of Cyclic Terminals in Polymers Obtained by Strong Base Initiation

M. Terbojevich, G. Pizzolo, E. Peggion, A. Cosani, and E. Scoffone

*Contribution from the Institute of Organic Chemistry, University of Padua, Padua, Italy, and VIII Sez. Centro Nazionale di Chimica Macromolecolare, Padua, Italy. Received December 28, 1966*

**Abstract:**  $\gamma$ -Benzyl-L-glutamate N-carboxyanhydride was polymerized in DMF using C<sup>14</sup>-labeled amines as initiators. All the radioactivity was incorporated in the polymers obtained by C<sup>14</sup>-isopropylamine initiation, indicating that normal primary amine polymerization is operative in this case. No radioactivity was found in the polymers when C<sup>14</sup>-methyl-diisopropylamine was used as the initiator. The Bamford mechanism is operative in this case. Using C<sup>14</sup>-diisopropylamine both mechanisms are simultaneously operative. Polymers prepared by initiation with unlabeled diisopropyl- and methyl-diisopropylamine and treated with an excess of C<sup>14</sup>-labeled isopropylamine exhibit considerable radioactivity. This radioactivity must be due only to reaction between the labeled amine and cyclic terminal present in the polymers.

On the basis of extent of the radioactivity incorporated in polymers "killed" with C<sup>14</sup>-labeled isopropylamine, the number of polymer molecules containing cyclic terminals, *i.e.*, formed *via* Bamford mechanism, was estimated. It was found that cyclic terminals deactivate *after* the end of the polymerization.

In previous papers<sup>1,2</sup> we presented evidence of the existence of bifunctional intermediates in the polymerization of N-carboxyanhydride (NCA) in dimethylformamide (DMF) initiated by strong bases. We found that when the polymerization mixture at 95% conversion is concentrated, a marked increase in molecular weight of the polymer is observed. We interpreted this fact assuming that coupling between bifunctional species occurs during concentration. These species are

formed if initiation and propagation occur *via* "active monomer" mechanisms, as suggested by Bamford<sup>3</sup> and Szwarc.<sup>4</sup>

This paper presents definitive evidence for the Bamford-Szwarc mechanism in the case of NCA polymerization initiated by strong base type initiators in DMF.

Moreover, further support for the "normal primary amine" addition mechanism is presented when primary amines are used as the initiators. The work has been carried out using radioactive amines.

## Experimental Section

**Materials.** Dimethylformamide (DMF) reagent grade was distilled under vacuum, over phosphorus pentoxide, immediately before use. DMF not freshly distilled was able to induce the polymerization of  $\gamma$ -benzyl-L-glutamate N-carboxyanhydride without addition of the initiator. Ethyl ether was refluxed over sodium metal and then distilled. Isopropylamine (IPA), diisopropylamine (DIPA), and methyl-diisopropylamine (MDIPA) were of reagent grade. They were dried over potassium metal and then fractionally distilled. Monomer  $\gamma$ -benzyl-L-glutamate N-carboxyanhydride (NCA) was prepared according to the literature.<sup>5</sup>

**Labeled Amines.**  $C^{14}$  IPA, DIPA, and MDIPA hydrochlorides were prepared as previously described.<sup>6</sup> The free  $C^{14}$  amines were obtained by exchange between the labeled hydrochlorides and the corresponding unlabeled pure amines. Radioactive standardization was carried out as previously described.<sup>7</sup>

**Radioactivity Measurements.** Weighed samples of polymer were dissolved in a known volume of freshly distilled, anhydrous DMF. These solutions were mixed with the phosphor solution (5 g of 2,5-diphenyloxazole and 0.5 g of 1,4-bis[2-(5-phenyloxazolyl)]benzene) in 1 l. of toluene. The radioactivity measurements were performed at  $-20^\circ$  using a SELO scintillation counter with super-scaler at 1020 v and bias at 5 v.

**Initiation with Labeled Amines.** i. **Physical Adsorption Checks.** Some preliminary checks were carried out in order to determine the physical adsorption of the labeled initiators on the polymers.

A typical experiment was as follows. To a solution of preformed polymer (500 mg) in DMF (25 ml)  $C^{14}$ -labeled IPA was added in an amount corresponding to that used to initiate polymerization. The mixture was stirred vigorously, and after 1 hr the solvent and the radioactive amine were evaporated under vacuum. The polymer was then dissolved in methylene chloride and precipitated by pouring the solution into ethyl ether. The polymer was isolated by filtration, redissolved in methylene chloride, and treated with a large excess of unlabeled IPA. The polymer was finally precipitated by pouring the solution into ethyl ether. Dissolution in methylene chloride, treatment with unlabeled IPA, and precipitation were repeated four times. The final polymer had only 0.5% (or less) of adsorbed radioactive amine. Analogous experiments were carried out with  $C^{14}$ -labeled DIPA and MDIPA with identical results.

ii. **Polymerization.** Poly- $\gamma$ -benzyl-L-glutamate (PBLG) samples were prepared by NCA polymerization in DMF using proper  $A/I$  ratios (see Table II). The radioactive initiators were introduced by direct distillation into the reaction mixture cooled at  $-190^\circ$ . The exact amounts of initiators used were determined by counting the total radioactivity of the polymerization mixtures. When the conversion reached at least 98% (checked by infrared) each polymerization mixture was divided in two parts. The first was treated according to procedure A and the second treated according to procedure B.

**Procedure A.** One-half of the reaction mixture was treated with a large excess of unlabeled IPA. Then the amine and solvent were distilled out, and the polymer was redissolved in methylene chloride and precipitated by pouring the solution into ethyl ether. Redissolution in methylene chloride, treatment with an excess of unlabeled initiating amine, and reprecipitation were repeated four times in the same way as described in Adsorption Checks.

**Procedure B.** One-half of the reaction mixture was concentrated to an oil in a rotating evaporator, diluted with methylene chloride, and precipitated by pouring into ethyl ether. The polymer was then redissolved, treated with an excess of unlabeled initiat-

ing amine, and reprecipitated; this procedure was repeated four times.

**Killing Experiments with  $C^{14}$ -Labeled Isopropylamine.** i. **Adsorption Test.** Polymer (230 mg) and 275 mg of monomer  $\gamma$ -benzyl-L-glutamate NCA were dissolved in 21 ml of DMF and treated with 2.5 ml of  $C^{14}$ -labeled IPA. After 1 hr the radioactive amine was distilled out and 2.5 ml of unlabeled IPA was added to the solution. After 1 hr the amine was again distilled out. The treatment with unlabeled IPA was repeated four times. Finally, all solvent was evaporated. The polymer was then redissolved in methylene chloride, treated with unlabeled IPA, and precipitated by pouring the solution into ethyl ether. Solution in  $CH_2Cl_2$ , treatment with unlabeled IPA, and precipitation into ethyl ether were repeated four times. The final polymer exhibits no trace of radioactivity. This means that the above procedure completely eliminates contamination of the polymer due to radioactive amine or to the product (ether soluble)

formed by reaction of the radioactive amine with the monomer.

ii. **Killing.** Two polymerization experiments were carried out in DMF using unlabeled DIPA and MDIPA as the initiators. In both cases the following polymerization conditions were used: monomer, 0.500 g; DMF, 25 ml; molar ratio of monomer to initiator,  $A/I$ , 20.

At various times of reaction, portions of the polymerization mixtures were taken away. Each portion was divided in two parts. The first was treated with 3 ml of  $C^{14}$ -labeled IPA. The polymer was then recovered according to the laborious procedure described in Adsorption Test.

The second was concentrated to an oil in a rotating evaporator; the polymer was redissolved in methylene chloride and precipitated by pouring the solution into ethyl ether.

**Molecular Weight Determinations.** Molecular weights ( $\bar{M}_w$ ) of the polymers were determined by viscometry in dichloroacetic acid solution (a Ubbelohde viscometer was used) using Doty's relation<sup>8</sup>  $[\eta] = 2.78 \times 10^{-5} \bar{M}_w^{0.57}$ .

## Results and Discussion

**Initiation.** Table I shows the results of polymerization experiments carried out in DMF using  $C^{14}$ -labeled initiators. These results are qualitatively similar to those obtained with the same monomer and initiators in dioxane.<sup>7,9</sup>

From these data it is evident that IPA mainly behaves like a "normal primary amine" initiator while MDIPA behaves like a strong base type initiator.

Both mechanisms appear to be operating simultaneously using  $C^{14}$ -DIPA. In this case we can roughly estimate the fraction of labeled molecules in the polymeric mixture. In fact, assuming  $\overline{DP}_n = 0.5\overline{DP}_w$  (this assumption is justified by our previous work),<sup>1</sup> the number of polymer molecules per 100 mg of polymer can be calculated. The experimental radioactivity measured on the polymer is directly proportional to the number of polymer molecules containing labeled initiator at their ends. It is easy to verify that the ratio between the per cent of initial radioactivity present in the polymers and the quantity  $T = (A/I)(100/\overline{DP}_n)$  gives directly the number fraction of labeled polymer molecules in the polymeric mixture. From Table II it can be seen that, by DIPA initiation, 5–10% of polymer molecules contain labeled initiator at their end, i.e., have been formed *via* the "primary amine" mechanism. Of course these values must be considered as roughly approximate.

**Presence of Cyclic Terminals in Polymers Obtained with Strong Bases Type Initiators.** The most serious objection to the Bamford-Szwarc mechanism was the lack of experimental evidence of the ring compound at the end of the polymer.<sup>4</sup>

The occurrence of coupling phenomena in polymers obtained in DMF using DIPA as the initiator was the first experimental evidence that bifunctional intermediates, I, do exist.<sup>1,2</sup> Also, from the data of Table I large differences appear between  $\bar{M}_w$  of polymers obtained by "killing" with IPA and polymers obtained by concentration of the reaction mixture before precipitation. We explained the higher  $\bar{M}_w$  of the "concentrated" polymers by the extensive occurrence of coupling reactions between bifunctional intermediates. *Coupling does not occur for polymers initiated by IPA, indicating that, in this case, no cyclic terminals are generated.* Further evidence of the presence of cyclic terminals on polymers obtained by DIPA or MDIPA initiation arises from the following experiments. We ran two polymerization experiments in DMF under standard conditions as indicated in Tables III and IV. Portions of the reaction mixture were removed at different reaction times. All portions were divided in two parts. The first was treated with a large excess of  $C^{14}$ -labeled IPA. Then amine and solvent were evaporated. The polymer was then recovered as described in the Experimental Section.

The second was concentrated in a rotating evaporator, treated with methylene chloride, and then poured into dry ether.

In Tables III and IV it is shown that all polymers "killed" with  $C^{14}$ -labeled IPA exhibit marked radioactivity. As described in the Experimental Section, the procedure we used in these experiments excludes the

<sup>a</sup> Calculated as in Table III.

presence of radioactivity due to adsorption and to the presence of by-products of reaction between the residual unreacted monomer and radioactive amine or between the side chain of the polymer and radioactive amine.

Our results can be explained only by admitting the presence of cyclic terminals on the polymer chains

which react with the excess of radioactive amine leading to radioactive polymer.

An important fact emerges from the data of Tables III and IV. The extent of radioactivity incorporated in the "killed" polymers depends on the time at which the excess of radioactive amine has been added to the solution. For example, the first sample of Table III, killed at 70% conversion, contains  $1.74 \times 10^{-3}$  mmole of labeled amine per 100 mg of polymer. In the sample killed 24 hr after the beginning of the reaction, the amount of incorporated amine is  $0.11 \times 10^{-3}$  mmole per 100 mg of polymer. From the amounts of incorporated amine it is possible to calculate the percentage of polymer molecules containing cyclic ends. These calculations are reported in the last columns of Tables III and IV. From these data it appears clearly that the percentage of molecules with cyclic terminals decreases also *after* the practical end of the polymerization. Moreover, we must point out that the progressive deactivation of the cyclic terminals is not due to the coupling reaction between bifunctional intermediates. In fact, after the practical end of the polymerization, the molecular weight is substantially the same in all the samples killed at different times. The coupling reaction occurs only in the portions of reaction mixture concentrated in the rotating evaporator.

On the bases of all the above observations we can now explain the  $\bar{M}_w$  data of killed and concentrated samples of Tables III and IV. In fact immediately after the end of the reaction, there is a large number of polymer molecules with cyclic terminals. Therefore, the concentration of the reaction mixture at this point induces a large increase in the  $\bar{M}_w$  of the polymer due to the coupling reaction. About 24 hr after the beginning of the polymerization, a large fraction of cyclic terminals was deactivated. As a consequence, no important coupling reaction occurs by concentrating the polymerization mixture, and there are no substantial differences between  $\bar{M}_w$  of "killed" and "concentrated" samples.

It is significant that if we treat with  $C^{14}$ -IPA the "concentrated" polymers, in which a large number of cyclic terminals disappeared because of coupling reactions, very little radioactivity goes into the polymers. The results of such an experiment are shown in Table V. These data clearly indicate that a very small number of cyclic terminals is still present in the "concentrated" polymers.

Reaction time, hr	Conversion, %	$\bar{M}_w$ of the concd sample	Radioactivity incorporated in the sample treated with labeled IPA, (100 mg of polymer)
0.5	80	60,000	4.

## Conclusions

The data presented in this work allow us to conclude that  $\gamma$ -benzyl-L-glutamate NCA polymerizes in accordance to the Bamford mechanism when tertiary amines are used as initiators. In fact, we prove bifunctional intermediates do exist and that cyclic terminals are present in polymer molecules. The normal primary amine mechanism is operative over the normal primary amine mechanism is operative with IPA as the initiator. Finally, both mechanisms are simultaneously operating with DIPA amine initiation.

We pointed out that in the case of strong base polymerization, cyclic terminals deactivate *after* the end of the reaction. Since DMF not freshly distilled was used to induce NCA polymerization without additional initiator, we suggest that deactivation occurs by reaction of cyclic terminals with impurities originating from solvent decomposition.

It is remarkable to observe that by MDIPA initiation we found only 70% of polymer molecules having cyclic terminals at 60% conversion. These findings are explained by the fact that cyclic terminals also appear during the polymerization by reaction with impurities. This termination reaction could be responsible for the presence of unlabeled polymer molecules in the killed polymers.

Also in the case of DIPA initiation, the percentage of polymer molecules with cyclic terminals is quite low. In this case, chain termination and the partial operation of the "primary amine" mechanism can account for the low extent of polymer chains with cyclic terminals.

## Reaction of Carbon Monoxide at Atmospheric Pressure with Trialkylboranes. A Convenient Route to Trialkylcarbinols via Hydroboration

Carbon monoxide at atmospheric pressure readily at 100–125° with trialkylboranes, synthesized in diglyme solution, to provide a convenient, old synthetic route to the corresponding trialkylcarbinols (1). In this way olefins, such as 2-butene,

cyclohexene, and norbornene, may be readily converted to highly hindered tertiary alcohols, tri-*sec*-butyl-, tricyclohexylcarbinol, and tri-2-norbornyl-, products available only in very low yield by classical Grignard synthesis.

As recently reported by Hillman that trialkylboranes react with carbon monoxide at high pressures in the range of 500 atm to give products oxidizable to trialkylcarbinols.<sup>1</sup> When the reaction was attempted at atmospheric pressure, only low yields of alcohols were obtained, less than 40% after 24-hr reaction.

Trialkylboranes are now readily available via the hydroboration of olefins.<sup>2</sup> It was therefore apparent that carbonylation of trialkylboranes thus prepared would offer a versatile route to the corresponding trialkylcarbinols. However, the apparent necessity of carrying out the carbonylation at high pressures represented a severe inconvenience for laboratory synthesis. Accordingly, we undertook to explore the possibility of accomplishing the carbonylation stage at atmospheric pressure in the same flask utilized for the hydroboration, using the automatic hydrogenator previously described<sup>3</sup> as adapted for carbonylations.<sup>4</sup>

When tri-*n*-octylborane in diglyme solution (0.5 M) and standard substrate, we observed that at 25° approximately 1 mole of carbon monoxide was absorbed per mole of trialkylborane. The reaction was indeed complete absorption of the gas requiring some 5 hr. However, the rate of absorption increased with increasing temperature, so that at 125° complete carbonylation could be achieved in 3 hr. These results are summarized in Figure 1. The reaction mixture obtained in the carbonylation at 125° was oxidized with alkaline hydrogen peroxide, producing tri-*n*-octylcarbinol in 90% yield.

To explore the scope of this convenient synthesis, a series of representative olefins were hydroborated and the resulting organoboranes were carbonylated *in situ* in the presence of ethylene glycol.<sup>5</sup> The reac-

tion mixtures were then oxidized with alkaline hydrogen peroxide and the trialkylcarbinols isolated.

It is noteworthy that this procedure yields trialkylcarbinols with highly branched alkyl groups, products which cannot be obtained in satisfactory yield by the methods presently available. Thus, 2-butene and isobutene were converted into tri-*sec*-butylcarbinol and triisobutylcarbinol in yields of 87 and 90%, respectively. Similarly, cyclopentene was converted into tricyclopentylcarbinol in 90% yield, and cyclohexene was converted into tricyclohexylcarbinol in 80% yield (2).

For comparison, tricyclohexylcarbinol is obtained in 7% yield from cyclohexyl chloride via the Grignard synthesis,<sup>6</sup> and the yield is increased to 19% by the use of a special procedure involving sodium.<sup>7</sup> Finally, 2-norbornylmagnesium halides rapidly equilibrate to a mixture of *exo* and *endo* derivatives.<sup>8</sup> The hydroboration product of norbornene is known to provide the essentially pure tri-*exo*-norbornylborane.<sup>9</sup> This was rapidly converted into a crystalline tri-2-norbornylcarbinol, melting sharply at 137–137.5°. Although we did not establish the stereochemistry, it is highly probable from previous experience with organoboranes<sup>3</sup> that the reaction proceeds with retention to yield tri-

*exo*-norbornylcarbinol (3). The experimental results are summarized in Table I.

The following procedure describing the conversion of norbornene into tri-2-norbornylcarbinol is representative. A dry 500-ml flask equipped with a septum inlet, thermometer well, and magnetic stirrer was attached to the carbonylation apparatus,<sup>9</sup> set up as previously described.<sup>4</sup> The system was flushed with nitrogen. A solution of 2.84 g (75 mmoles) of sodium borohydride in 150 ml of diglyme was introduced, followed by 28.3 g (300 mmoles) of norbornene. The flask was immersed in an ice-water bath and the hydroboration achieved by the dropwise addition of 27.4 ml (100 mmoles) of boron trifluoride diglymate.<sup>10</sup> The

(5) In most cases the reaction proceeded satisfactorily in the absence of added ethylene glycol. In some cases, however, we noted the formation of a less reactive, possibly polymeric, intermediate. The presence of the ethylene glycol circumvented this difficulty.

#### Reaction of Carbon Monoxide at Atmospheric Pressure with Trialkylboranes in the Presence of Water. A Convenient Synthesis of Dialkylketones via Hydroboration

Sir:

In the preceding communication we reported trialkylboranes in diglyme solution react readily with carbon monoxide at atmospheric pressure. Oxidation of the organoboron intermediate with alkaline hydrogen peroxide provides the trialkylcarbinols in excellent yields.<sup>1</sup>

We now wish to report that the addition of quantities of water to the reaction mixture inhibits migration of the third alkyl group from boron to carbon.<sup>2</sup> Consequently, oxidation of the organoboron intermediate obtained in the presence of water produces the corresponding dialkyl ketone, instead of the trialkylcarbinol realized in the reaction in the absence of (1).

The following results illustrate the marked effect of the presence of relatively small quantities of water. Carbonylation of 100 mmoles of tri-*n*-butylborane in diglyme solution at 100° in the absence of any water produces 60 mmoles of tri-*n*-butylcarbinol and 40 mmoles of di-*n*-butylketone. In the presence of 1 g of water (150 mmoles) under otherwise identical conditions oxidation of the reaction mixture with alkaline hydrogen peroxide produces 90 mmoles of *n*-butyl ketone, 100 mmoles of *n*-butyl alcohol, and 10 mmoles of tri-*n*-butylcarbinol (2).

(1) H. C. Brown and M. W. Rathke, *J. Am. Chem. Soc.*, **89**, 1 (1967).

(2) M. E. D. Hillman, *ibid.*, **84**, 4715 (1962), utilized excess diglyme as a reaction medium for the carbonylation of primary trialkylboranes and was able to control the migration of alkyl groups during carbonylation at high pressures by operating between 75° (transfer of two groups) and 150° (transfer of three groups).

sequently, the carbonylation in the presence of ester of organoboranes, now readily synthesized by hydroboration,<sup>8</sup> provides a highly convenient synthetic route to ketones.<sup>4</sup>

The scope of the reaction was explored with representative aliphatic, alicyclic, and bicyclic olefins. In the case of 2-butene was readily converted into di-*sec*-butyl ketone, cyclopentene into dicyclopentyl ketone, cyclohexene into dicyclohexyl ketone, and norbornene into di-2-norbornyl ketone<sup>6</sup> (4), in yields of 80–90%.

The results are summarized in Table I.

The following procedure for the conversion of cyclopentene into dicyclopentyl ketone is representative. The apparatus was set up as described previously.<sup>1</sup> A solution of 20.4 g (300 mmoles) of cyclopentene in 100 ml of diglyme was introduced into the flask and the flask cooled with an ice-water bath as hydroboration was achieved by the dropwise addition of 50 ml of a solution of borane in tetrahydrofuran.<sup>6</sup> The

product is probably di-*exo*-norbornyl ketone. However, we are currently exploring the synthesis of cyclic, bicyclic, and derivatives utilizing this reaction. These results will be reported in the near future.

The presence of water is presumed to convert the hypothetical boraepoxide III into the hydrate V. Oxidation produces the ketone.<sup>7</sup>

solution was stirred at room temperature for 1 hr. The tetrahydrofuran was removed by distillation under reduced pressure. Water (2.7 ml, 150 mmoles) was then added, and the solution was brought to 100°. The system was flushed with carbon monoxide, and reaction was initiated by magnetically stirring the contents of the flask. Absorption of the carbon monoxide proceeded automatically and ceased after 2.5 hr. The flask was then cooled in an ice-water bath and oxidation accomplished by the addition of 3 *N* sodium hydroxide followed by dropwise addition of 23 ml of 30% hydrogen peroxide, keeping the temperature under 35°. After the addition had been completed, the reaction mixture was stirred for an additional hour at 30 to 35°. The solution was poured into 300 ml of water and extracted once with 100 ml of pentane. The pentane solution was back-extracted twice with 300-ml portions of water to remove diglyme. The pentane solution was dried over calcium hydride and vacuum distilled. There was obtained 15.0 g (90%) of dicyclopentyl ketone, bp 86° (5 mm).

Although we have been too preoccupied with exploring the scope of this synthetic approach to investigate the mechanism, we can rationalize the results in terms of the following mechanism adapted from that previously suggested by Hillman<sup>2</sup> (5). In the absence

of hydroxylic solvents III can readily dimerize into the 2,5-diboradioxanes, isolated by Hillman, or undergo migration of the third alkyl group to give the intermediate IV, isolated by Hillman as the trimeric boroxine. The intermediate IV, or the ester produced by reaction of IV with ethylene glycol, or the trimeric boroxine are all oxidized to the trialkylcarbinol and boric acid by alkaline hydrogen peroxide. Under our conditions all three alkyl groups migrate unless something is done to inhibit the migration of the third group.

The presence of water is presumed to convert the hypothetical boraepoxide III into the hydrate V. Oxidation produces the ketone.<sup>7</sup>

The presence of water is presumed to convert the hypothetical boraepoxide III into the hydrate V. Oxidation produces the ketone.<sup>7</sup>

According to this mechanism, the successful trapping of intermediate II would provide a valuable means of converting olefins into their methylol derivatives. This is described in the following communication.<sup>8</sup>

(7) Hillman realized only dialkylcarbinols in his oxidations, with only traces of dialkyl ketones. We are unable to account for the difference between his results and our own, unless the presence of the diglyme protects the intermediate V from the hydrolysis by the base prior to the addition of the hydrogen peroxide. We have been able to obtain dialkylcarbinols by subjecting the reaction product to hydrolysis with aqueous alkali at elevated temperatures prior to oxidation with alkaline hydrogen peroxide.

### Reaction of Carbon Monoxide at Atmospheric Pressure with Trialkylboranes in the Presence of Sodium or Lithium Borohydride. A Convenient Procedure for the Oxymethylation of Olefins *via* Hydroboration

Sir:

We wish to report that both sodium and lithium borohydrides markedly catalyze the rate of absorption of carbon monoxide at atmospheric pressure by trialkylboranes in ether solvents. The reaction can be controlled to achieve the transfer of but one alkyl group from boron to carbon. Consequently, hydrolysis of the reaction intermediate with ethanolic potassium hydroxide produces the homologated alcohol (1).

Consequently, carbonylation of organoboranes can now be controlled to achieve migration of all three groups from boron to carbon, providing the trialkylcarbinol;<sup>1</sup> two groups, providing the ketone or dialkylcarbinol;<sup>2</sup> or one group, providing the corresponding methylol derivative of the olefin.

By means of this latter reaction, described in this communication, we have been able to achieve the conversion of 1-octene into 1-nonanol, cyclopentene into cyclopentylmethanol, cyclohexene into cyclohexylmethanol, and norbornene into 2-*exo*-norbornylmethanol, in yields of 70–85%.

In previous experiments<sup>1,2</sup> we found it necessary to operate at 100–125° in order to achieve absorption of carbon monoxide by trialkylboranes at a convenient rate. However, the rate of absorption is markedly enhanced by the presence of alkali metal borohydrides. Thus, the presence of 200 mmoles of sodium borohydride in a solution of 100 mmoles of triethylborane in 100 ml of diglyme caused the uptake of carbon monoxide to be complete in 1 hr at 45°. Hydrolysis with

Table I. The Reaction of Carbon Monoxide at Atmospheric Pressure with Solutions of Triethylborane (1.00 M) at 45° Presence of Varying Amounts of Sodium Borohydride

Sodium borohydride, mmoles	Triethylborane, mmoles	Carbon monoxide absorbed, mmoles	Products, mmol	P
200	100	142	180	
100	100	142	195	
50	100	140	202	
25	100	81	240	

ethanolic potassium hydroxide, followed by ox with hydrogen peroxide, produced 180 mmoles anol, 80 mmoles of 1-propanol, and 12 mmole ethylcarbinol. No trace of 1-butanol, corresponding to the doubly homologated alcohol, was found analysis.<sup>3</sup>

It is possible that the borohydride function reducing the initially formed carbonyl (I) of the

posed mechanism.<sup>2</sup> This would be followed by transfer of one alkyl group from boron to carbon. However, at this stage we were more concerned with exploring the scope of this new synthesis than in investigating the mechanism.

The data summarized in Table I indicate the stoichiometry for sodium borohydride to be 0.5NaBH<sub>4</sub>/

Analysis of the solutions for residual hydride indicated the following over-all stoichiometry (2).

The amount of carbon monoxide consumed in these reactions is not yet understood. We observed approximately 1.5 moles of carbon monoxide to be sorbed per mole of trialkylborane in all cases tested, although the homologated alcohols isolated as major product, plus the much smaller by-product dialkylcarbinol, accounted for only 1 mole gas. Possibly the excess consumption of carbon monoxide is the result of a direct reduction by an intermediate.

The observation that the reaction proceeds rapidly at 45° suggested the desirability of utilizing the most convenient solvent, tetrahydrofuran, for both the hydroboration and carbonylation stages. Lithium borohydride was therefore selected for its solubility in this solvent. Results obtained with this system are summarized in Table II.

The following procedure for the synthesis of 2-norbornylmethanol is representative. A dry flask, equipped with thermometer well, septum and magnetic stirrer, was attached to the carbon monoxide apparatus, set up as previously described.<sup>1</sup> The flask was flushed with nitrogen. Then, a solution of (150 mmoles) of norbornene in tetrahydrofuran (200 ml) was introduced into the flask and the flask was immersed in an ice-water bath. Hydroboration was achieved by adding dropwise 23.4 ml of a solu-

(3) The convenient synthesis of homologated alcohols by reaction of dimethyloxosulfonium methylide with trialkylboranes has recently been reported: J. J. Tufariello and T. L. C. Lee, *ibid.*, **89**, 2738 (1967). However, this procedure produces appreciable amounts of the higher homologated alcohols.

## Photochemistry. II. The Photosensitized Addition of Butadiene to acrylonitrile<sup>1</sup>

ugh the photosensitized cross-addition of dieno-to olefins is well-known,<sup>2</sup> the corresponding

I: W. L. Dilling, *Chem. Rev.*, **66**, 373 (1966).

photosensitized addition of dienophiles to dienes is much less common. Examples of the latter reaction have been confined to the addition of dienes to  $\alpha,\beta$ -unsaturated carbonyl compounds,<sup>3</sup> other dienes,<sup>4</sup> the haloethylenes,<sup>5</sup> and a simple olefin.<sup>6</sup> The photosensitized dimerization of the dienes themselves<sup>4a,7</sup> (the predominant reaction even in the presence of dienophiles<sup>5,6</sup>) may be regarded as a special case, but other examples are lacking, and the reaction has not yet been demonstrated to be general.<sup>6</sup>

The major products from these photosensitized diene-dienophile cross-additions are solely<sup>3a,b,d</sup> or predominantly<sup>3c,4,5</sup> cyclobutanes with the exception of the photosensitized addition of 1,3-cyclohexadiene to cyclopentene<sup>8</sup> (a poor dienophile<sup>9</sup>). When cyclohexenes are formed, they appear to be different (e.g., *exo* rather than *endo* in the case of cyclic dienes<sup>3c</sup>) from the expected Diels-Alder (thermal) adducts. This fact, plus the observation of entirely different product ratios when the expected Diels-Alder adducts are formed, has led to the postulate that the photo- and thermal adducts result from quite different reaction paths.<sup>3c,5,7b,b</sup>

We now wish to report what appears to be the first photosensitized cycloaddition of an  $\alpha,\beta$ -unsaturated nitrile to a simple diene to yield products *identical* with those formed in the thermal (Diels-Alder) reaction, albeit in different ratios.

Irradiation of an equimolar mixture of butadiene (1) and  $\alpha$ -acetoxyacrylonitrile (2) in the presence of 0.2 mole of a sensitizer through 7740 Pyrex glass ( $\lambda > 280$  m $\mu$ )<sup>9</sup> with a 450-w medium-pressure Hanovia mercury arc lamp at ca. 30° gave the three cross-adducts 3-5 (in yields of 30-50% of the total dimeric products, depending on the sensitizer<sup>10</sup>), previously observed from the thermal reaction,<sup>11</sup> along with the three butadiene dimers 6-8.<sup>7i,12</sup> The products were identified

(12) At butadiene conversions greater than ca. 20%, depending on the sensitizer, a copolymer of 1 and 2 was also formed. The products of the reaction, 3-8, were relatively stable under the reaction conditions

by comparison of their gas chromatographic retention times with those of authentic materials.<sup>7f,11</sup> Also the nmr and infrared spectra of samples isolated by preparative gas chromatography were compared with the spectra of authentic materials.<sup>12</sup>

The product distributions for various sensitizers are reported in the accompanying communication.<sup>10</sup> For the present discussion, let it suffice to say that the cyclohexene 5 constituted 2–31% of the total cross-adducts 3–5, while the thermal reaction of 1 and 2 at 125–190° gave 77–91% 5. We interpret the fact that the cyclohexene 5 is formed at all in the sensitized cross-addition to indicate that the cyclohexene can arise *via* a two-step reaction.<sup>11,14</sup>

Experiments on the unsensitized (direct irradiation through quartz<sup>15</sup>) photoreaction of 1 and 2 indicated that of the cross-addition processes only 1,2 addition occurred, probably *via* the excited singlet state of the diene 1.<sup>16</sup>

**Acknowledgment.** The authors wish to thank Mr. K. C. Whitman and Mr. F. L. Beman and co-workers for experimental assistance.

employed in this study. The conversions were kept low to avoid complications due to possible further reactions of the products. Another side reaction was observed when camphorquinone was used as the sensitizer. This sensitizer undergoes a photoreaction with butadiene to give a product which we have tentatively identified as a vinyloxetane (possibly several isomers) arising from the addition of one carbonyl group of triplet camphorquinone to one butadiene double bond. We have measured the (3 + 4):5 ratio at different stages of conversion and find no significant change.<sup>13</sup>

(13) The *cis*-divinylcyclobutane (7) was isolated as the thermal rearrangement product, 1,5-cyclooctadiene.<sup>7f</sup>

### Organic Photochemistry. III. 1,2 vs. 1,4 Addition as a Function of Sensitizer Triplet Energy in a Cross-Addition Reaction<sup>1</sup>

Sir:

In the preceding communication<sup>1</sup> we described the photosensitized cycloaddition of the diene 1 to the

(1) Part II: W. L. Dilling and J. C. Little, *J. Am. Chem. Soc.*, **89**, 2741 (1967).

olefin 2.<sup>2</sup> In this communication we report the of the sensitizer triplet energy on the product distribution.

The product distribution between the 1,2-di cyclobutanes and the 4-vinylcyclohexenes in the p sensitized dimerization of butadiene or isoprene been shown to be dependent on the triplet energy of sensitizer.<sup>3</sup> This dependence was attributed to difference in the energy levels of the *cis*- and *trans*- triplets,<sup>4</sup> the *trans* forms giving mostly cyclobutane the *cis* forms giving relatively large amounts of hexenes.

The product distributions for the cross-addition and 2 with various sensitizers are given in Table 1. The relative amount of cyclobutanes 3 and 4 in the cross-adducts 3–5 as a function of the sensitizer triplet energy is shown in Figure 1 along with the curve obtained by Hammond and co-workers<sup>3c</sup> for the dimerization of butadiene (1).

In general, our results on the cross-addition parallel quite closely those for the dimerization except for the depth of the minimum in the amount of cyclobutane in the 50-kcal/mole region. The breaking point at 50 kcal/mole can be explained, as in the case of dimerization,<sup>3c</sup> by the *s-trans*- and *s-cis*-butadienes having lowest triplet energy levels at 59.6 kcal/mole<sup>3c</sup>, ca. 53 kcal/mole,<sup>3b,c</sup> respectively.<sup>6</sup> The increase in the relative amount of cyclobutanes with sensitizers having triplet energies lower than 50 kcal/mole could be due to "nonvertical" excitation, as has been proposed for butadiene and isoprene dimerizations.<sup>3c</sup>

We attribute the difference in the relative amount of cyclobutanes formed in the cross-addition and dimerization in the 50-kcal/mole region of Figure 1 to the difference in selectivity of ring closure of the *s-cis* triplet adduct, a, and the *s-cis*-1-1 adduct, b (Scheme 1). If the reasonable assumptions are made that the relative amounts of *cis* and *trans* triplets are proportional for any one sensitizer whether the olefin 2 is present or not, and that the reactivity of the two isomeric triplets with 2 (and with 1) are the same, then the difference in product distribution must reflect the difference in reactivity of ring closure of intermediates a and b. In the cross-intermediate, a, closed to a four-membered ring, 3 or 4, to a greater extent than did the intermediate, b. It has been shown from experiments that cross-termination between unlike radicals is favored over termination between like radicals, to a rather large extent.<sup>7</sup> Thus the coupling of unlike radicals such as the ring closure of a (with electron paired) is probably faster and therefore less selective than the coupling of like radicals as in b (with electron paired). Since the intermediates a and b can exist

(2) The numbering system in ref 1 is retained in this paper.

## A New Peptide Coupling Reagent

Sir:

In recent years the potential utility of activated esters as coupling agents in peptide synthesis has been extended, first by the development of the isoxazolium salts and their derivatives<sup>1</sup> which generate enolic or

(1) (a) R. B. Woodward, R. A. Olofson, and H. Mayer, *J. Am. Chem.*

3-Acetoxy-2-hydroxy-N-ethylbenzamide (IIa)	1.485 (0.62), NH stretch	246 (6280) 299 (3800) 238 (8120)	326 (6530)	6.7

phenolic esters of peptide acids under convenient and mild conditions, and second by the discovery of peptide activated esters which discriminate effectively between aminolysis and racemization, even in polar solvents and under strongly basic conditions.<sup>3</sup> We wish to report the preparation of 2-ethyl-7-hydroxybenzoxazolium cation (I), a substance which combines both features in one system.

By means of procedures described previously,<sup>1b</sup> 2,3-dihydroxybenzaldehyde<sup>3</sup> can be converted in 75% yield to the fluoroborate salt of I, mp 136–137°. Addition of this salt as a powder to a vigorously stirred, chilled aqueous solution of sodium salts of carboxylic acids, overlaid with ethyl acetate and maintained at pH 4.5 with a pyridine buffer, results in the formation of 3-acyloxy-2-hydroxy-N-ethylbenzamides, II.<sup>6</sup> Reactions are complete within 5 min under these conditions ( $t_{1/2} < 1$  min, 25°,  $\text{H}_2\text{O}$ , pH 5) and the products can be isolated from the organic phase after acid and bicarbonate extractions. By analogy with the behavior of the 2-ethylbenzoxazolium cation (III),<sup>6</sup> the mechanism shown in Scheme I is assigned to this conversion. Under conditions which with III result in predominant azlactone formation,<sup>1b,c</sup> I combines with ZGly-L-PheOH to yield IIc with no detectable formation (<0.5%) of the corresponding azlactone; I thus provides a method of converting peptide acids to activated esters without concomitant racemization.

That structure II corresponds to the products of these reactions follows from a study of the acetic acid product. This substance, infrared 1645 and 1760  $\text{cm}^{-1}$ , whose spectra are compared in Table I with models, is also formed in 73% yield by aqueous acetylation of 2,3-dihydroxy-N-ethylbenzamide; its reaction with ethereal diazomethane-fluoroboric acid followed by hydrolysis yields 3-hydroxy-2-methoxy-N-ethylbenzamide.

Although otherwise similar to simple phenolic esters of peptide acids, peptide esters of structure II are remarkably resistant to racemization by tertiary amines. After 12 hr in dry DMF 0.4 M in triethylamine IIc is racemized to the extent of less than 1%.<sup>7</sup> Under

identical conditions O(-ZGly-L-Phe)-N-ethylsalicylamide is racemized over 4000 times faster.

Scheme I

The remarkable base stability of these esters suggested their use in coupling reactions with salts of amino acids. When IIb and the tetramethylammonium salt of L-phenylalanine were combined in dry DMF, a quantitative precipitation of L-phenylalanine occurred and the soluble tetramethylammonium salt of IIb was formed. Addition of excess L-phenylalanine salt resulted in a rapid reaction ( $t_{1/2} \sim 1.5$  min at 0.2 M amine), and isolation of the product after 15 min by addition of aqueous bicarbonate, extraction with ethyl acetate, and acidification yielded, after crystallization, 91% carbobenzoxyglycyl-L-phenylalanine, mp 129–130°,  $[\alpha]_D^{25} + 39.9^\circ$  (c 2.0, EtOH). Similarly, the tripeptide acid carbobenzoxyglycyl-L-phenylalanylglycine was obtained in 89% yield, mp 162–163°,  $[\alpha]_D^{25} - 14.8^\circ$  (c 1.3, EtOH), by condensation of IIc with glycine tetramethylammonium salt in DMSO. As a test of optical purity,<sup>6</sup> the tripeptide acid was dissolved in aqueous base and converted with triethyloxonium ion to its ethyl ester in 60% yield; less than 0.5% of racemic ester was observed.

The favorable properties of these activated species appear to result from an interaction of several inde-

## ic Base Catalysis of Azlactone Formation

ent work<sup>1,2</sup> has established azlactones as essential ediates in the racemization of many peptide ed species. While this and earlier work has clear a dependence of azlactone formation on the ce of base, the precise nature of the dependence ot been explored. By analogy with Winstein's on the cyclization of 2-benzamidoethyl tosylates,<sup>3</sup> ould anticipate for a primary or secondary amide l nucleophilicity, dependent on the relative onditions of neutral amide and amide anion present ection medium. We wish to present evidence supports the presence of equilibrated amide s as the reactive intermediates leading to azlactone tion from four peptide activated esters.

le I presents first-order rate constants observed he triethylamine-catalyzed racemization of O-benzoxycyl-L-phenylalanyl)-N-ethylsalicyl- (Ia)<sup>4</sup> in dimethylformamide containing tri-

<sup>a</sup> Temperature 25°, DMF solvent. <sup>b</sup> Unless otherwise specified, sufficient Et<sub>3</sub>N<sup>+</sup>BF<sub>4</sub><sup>-</sup> was added to bring the total salt concentration to 0.2 M. <sup>c</sup> Ester concentration 10-20 mg/ml; rates followed polarimetrically, first-order rate law followed for at least three half-lives. <sup>d</sup> For rates at 0.2 M Et<sub>3</sub>N, a plot of the observed first-order rate constant vs. [Et<sub>3</sub>N]/[Et<sub>3</sub>N<sup>+</sup>H] was linear with a slope, *k*<sub>1</sub>, of 1.4 × 10<sup>-3</sup> min<sup>-1</sup> and a zero intercept, *k*<sub>0</sub>, of 2.3 × 10<sup>-3</sup>. Calculated rate = *k*<sub>1</sub>[Et<sub>3</sub>N]/[Et<sub>3</sub>N<sup>+</sup>H] + *k*<sub>0</sub>.

ethylammonium fluoroborate. The observed linear dependence of rate on the amine:amine salt ratio, together with the striking insensitivity of rate to the absolute amine concentration at constant amine:amine salt ratio, are most easily interpreted as requiring the intermediacy of a conjugate base of Ia. A scheme consistent with this result is shown below.<sup>7</sup>

$$d[\text{DL-Ia}]/dt = k_1[\text{L-Ia}'] = k_1K[\text{L-Ia}][\text{Et}_3\text{N}]/[\text{Et}_3\text{NH}^+] \quad (1)$$

Similar behavior is observed for the esters Ib, Ic, and II (Table II). It is of interest that the intercepts, *k*<sub>0</sub>, which are the limiting rates expected at constant amine concentration as the amine salt concentration is raised, most include all general base catalyzed terms; their magnitudes therefore bound the rates of simple base-catalyzed enolization for these esters. Although these results must be generalized with caution since they stand in contrast to other well-known salt effects on peptide racemization,<sup>8</sup> it would appear that in DMF tertiary amine catalyzed racemization of peptide phe-

(7) Although the formation of azlactones need not result in racemization, the reaction conditions of this study (polar solvent, excess of non-nucleophilic base) ensure that II racemizes faster than it reacts with phenolate anion, and therefore that *k*<sub>1</sub> is rate-determining.<sup>1</sup>

<sup>a</sup> Rates followed polarimetrically;  $\text{Et}_3\text{N} = 0.2 \text{ M}$ ,  $\text{Et}_3\text{N}^+\text{H} + \text{Et}_3\text{N}^+ = 0.2 \text{ M}$ , temperature  $25^\circ$ , DMF, anion =  $\text{BF}_4^-$ ,  $0.01 \leq [\text{Et}_3\text{N}^+\text{H}] \leq 0.2 \text{ M}$ ;  $k_a$  and  $k_b$  obtained as described in Table I, footnote *d*. <sup>b</sup> Rates of the reaction, ester + GlyOEt  $\rightarrow$  ZGly-Phe-GlyOEt + phenol; rates followed by ultraviolet photometry in DMF,  $30^\circ$ ; ester,  $1\text{--}2 \times 10^{-4} \text{ M}$ ; GlyOEt,  $0.01\text{--}0.5 \text{ M}$ ; reactions were first order in ester to at least three-half-lives, first order in amine over at least a 3-fold concentration range.

nolic esters can be slowed by as much as 50-fold by the addition of the corresponding ammonium fluoroborate salt.

Included in Table II are rates of combination of the esters Ia–c and II with ethyl glycinate in DMF. Since the value of  $K$  in (1) should not vary significantly for these esters, the values of  $k_a$  may be taken as measures of the relative reactivities of the esters Ia–c and II toward an internal oxygen nucleophile. Comparing these values with the rates of reaction with an external amine, one finds a surprisingly good correlation, despite considerable variation of reactivity and structure.

## A Valence Tautomer of Pyrene *cis*-15,16-Epoxyde

Sir:

Recently we reported the synthesis of *trans*-15,16-dimethyldihydropyrene<sup>1</sup> and its photoisomerization to the corresponding metacyclophane valence tautomer.<sup>2</sup> Since then, syntheses of other examples of *trans*-15,16-dihydropyrenes have been described,<sup>3,4</sup> but as yet no example has been reported of a *cis*-15,16-dihydropyrene derivative. We now wish to record the synthesis of 8,16-oxido[2.2]metacyclophane-1,9-diene (VIII), a valence tautomer of *cis*-pyrene 15,16-epoxide.

The starting material for this synthesis was xanthene-9-carbinol (I), which undergoes an acid-catalyzed rearrangement in essentially quantitative yield to give dibenz[b,f]oxepine (II).<sup>5</sup> Reduction of II gave the corresponding dihydro derivative III as a colorless oil, bp  $100\text{--}103^\circ$  (0.2 mm).<sup>6</sup> Treatment of III with *n*-butyllithium followed by carbonation, according to the procedure used by Gilman for carbonating diphenyl

ether,<sup>7</sup> gave the corresponding dicarboxylic acid w by reaction with diazomethane, led to the dimethyl IV as white crystals, mp  $94.5\text{--}95.0^\circ$ , in 39% ov yield. Reduction of IV with lithium aluminum hy provided the diol V as white crystals, mp  $123\text{--}125^\circ$  in 98% yield. Conversion of V to the correspo dibromide VI, white crystals, mp  $124\text{--}125^\circ$ , wa accomplished in 90% yield using phosphorus tribro Cyclization of VI with phenyllithium to the c sponding metacyclophane VII, mp  $94.0\text{--}95.5^\circ$ , curred smoothly in 75% yield.

Although VII is a metacyclophane derivative oxygen bridge forces the two benzene rings into relationship in contrast to the normal *trans* geomet [2.2]metacyclophanes.<sup>8</sup> Further, it could be exp that the *cis* geometry of VII would allow no benzylic substitution. This was found to be the Treatment of VII with 2 equiv of N-bromosuccini gave the corresponding dibromide as a mixture o stereoisomers. Without separation, this mixture then subjected to reaction with potassium *t*-butoxi *t*-butyl alcohol to yield the desired unsaturatec rivative, VIII, as white crystals, mp  $119\text{--}120^\circ$  support of its structural assignment, VIII showe A<sub>2</sub>B multiplet (6 H) at  $\tau$  2.66–3.30 and a singlet ( at  $\tau$  2.92. Also, the ultraviolet absorption spectru VIII showed absorption maxima in cyclohexane a ( $\epsilon$  15,700) and  $302 \text{ m}\mu$  ( $\epsilon$  16,300), indicating conjug between the aromatic rings and the unsaturated chains.<sup>9</sup>

Although the spectral data clearly establish that is the correct structure of our product and that s taneous valence tautomerization to the correspo pyrene 15,16-epoxide structure does not occur, it w interest to see whether conditions might be found accomplishing this valence tautomerization. initial attempts employing light and heat have

(6) Satisfactory elemental analyses have been obtained for all of the compounds reported in this communication.

success. However, when VIII is dissolved in acid, trifluoroacetic or sulfuric, the solution becomes deep green, the typical color of the *trans*-15,16-pyrene system. Furthermore, the absorption of such solutions in trifluoroacetic acid shows peaks at 470, 560, and 647 m $\mu$ , in good agreement with the spectra of *trans*-15,16-dimethyldihydropyrene derivatives.<sup>10</sup>

In view of the spectral correlations it is our belief that solutions of VIII in strong acid contain pyrene dioxide, the valence tautomer of VIII, presumably in its protonated form as shown by IX. The intensity of the green color increases to a maximum approximately 30 min after dissolving VIII in trifluoroacetic acid (temperature 30°); the intensity then decreases slowly with the rate showing first-order kinetics suggesting IX is formed fairly rapidly and then undergoes slow decomposition. From this solution 1,6-pyrenequinone, and 1,8-pyrenequinone have been isolated and identified chromatographically and spectroscopically.<sup>11</sup> We have found that a solution of VIII in trifluoroacetic acid is stable, but the hydrocarbon is oxidized at room temperature by pertrifluoroacetic acid to yield a mixture containing the two quinones.

These observations indicate that the cation IX is formed by loss of OH<sup>+</sup> to form pertrifluoroacetic acid and the pyrenequinones from VIII.

Since the absorption maxima of VIII are still present in the acid, it is not possible to give exact values for extinction coefficients. However, the relative intensities of the absorption maxima are in reasonable accord with those of the dihydroxy compound at 560 m $\mu$  being extremely weak. No assignment of overtone bands could be made due to the presence of VIII initially.

Formation of pyrene as the reaction progressed (see below).

## [2.2]Metacyclophane-1-ene<sup>1</sup> and Its Photoisomerization to 1,16-Tetrahydropyrene

Although Pellegrin<sup>2</sup> has claimed the synthesis of [2.2]metacyclophane-1,9-diene (I), subsequent attempts at its preparation have been unsuccessful.<sup>3,4</sup> Furthermore, even though the elegant studies of Dewar and Cram<sup>5</sup> have shown that [2.2]paracyclophane can be converted to the corresponding mono- and diolefinic compounds, attempts to utilize their procedure for introduction of unsaturation into the [2.2]metacyclophane molecule have been unsuccessful.<sup>4</sup> In view of our recent studies<sup>6</sup> on [2.2]metacyclophane-1,9-diene derivatives

undergo spontaneous valence tautomerization to the corresponding *trans*-15,16-dihydropyrene derivatives, it has become of interest to reexamine the synthesis of [2.2]metacyclophanes having unsaturation in the bridging atoms. We now report the successful preparation of [2.2]metacyclophane-1-ene (II).

I

II

Treatment of the monophosphonium salt of *m*-xylyl dibromide with methanol readily gives the corresponding methoxy derivative III, mp 242-242.5°.<sup>7</sup> The reaction of III with oxygen in the presence of base, following the procedure of Bestmann,<sup>8</sup> yielded a mixture of the *cis*- and *trans*-stilbenes, IV. Cleavage of the benzylic ether linkages of IV with hydrogen bromide gave the corresponding *trans*-dibromide V, mp 161-162°, which by reaction with sodium acetate led to the *trans*-diacetate VI, mp 97-98°. Irradiation converted VI to a mixture of stereoisomers whose nmr spectrum indicated the ratio of *cis* to *trans* isomers was 3:1. On addition of ethanol the *trans* form of VI crystallized out. Hydrolysis of the remaining *cis* isomer of VI gave the corresponding diol VII as an oil, which was characterized by its analytical and spectral data. Treatment of VII with phosphorus tribromide followed by chromatography of the product gave the pure *cis*-stilbene dibromide VIII as a colorless oil.

III

IV, Y = OCH<sub>3</sub>

V, Y = Br

VI, Y = OAc

VII, Y = OH

VIII, Y = Br

II

In devising this scheme it had been anticipated that the presence of a bridging double bond, if it were in the *cis* configuration, would not interfere but might even help in a cyclization to the corresponding metacyclo-

(7) Satisfactory elemental analyses and supporting spectral data have been obtained for all new compounds reported in this communication.

(8) H. J. Bestmann, *Angew. Chem.*, **72**, 34 (1960); H. J. Bestmann and O. Kratzer, *Chem. Ber.*, **96**, 1899 (1963).

phane. When VIII was treated with sodium in the presence of tetraphenylethylene, the usual conditions for cyclization to form metacyclophanes, cyclization occurred, but it was accompanied by aromatization to give 4,5-dihydropyrene (X) in 50% yield. However, an investigation of other cyclization procedures led to the discovery that the treatment of VIII with phenyllithium in ether gives the desired [2.2]metacyclophane-1-ene (II) as white crystals, mp 82–83°, in 45% yield. It is of interest that in the nmr spectrum of II the signal for the two internal aromatic protons at the 8 and 16 positions is a broad singlet at  $\tau$  4.38. In [2.2]metacyclophane itself the internal 8 and 16 protons appear at  $\tau$  5.75. Thus, the orientation of the bridging double bond is such that it has a strong deshielding effect on the internal aromatic protons.

Ultraviolet irradiation of stilbene solutions in the absence of oxygen has been shown by a number of investigators to lead to 4a,4b-dihydrophenanthrenes.<sup>9–13</sup> When a solution of II in benzene or carbon tetrachloride was irradiated with ultraviolet light, the solution rapidly became colored, showing the appearance of absorption bands at 237, 305, 318.5, and 500 m $\mu$  (broad).<sup>14</sup> This spectrum is in good accord with that reported for the hexamethyldihydrophenanthrene<sup>13</sup> and suggests the formation of the 4,5,15,16-tetrahydropyrene (IX). As would be expected, the formation of IX is readily reversible by visible light. Furthermore, the solutions resulting from irradiation of II are extremely sensitive to traces of oxygen and, in its presence, the product found is 4,5-dihydropyrene (X).

Thus far, attempts (catalytic dehydrogenation and NBS) to effect a dehydrogenation of IX to give *trans*-15,16-dihydropyrene have been unsuccessful and have invariably yielded pyrene. However, in the case where the internal substituents are other than hydrogen, the corresponding irradiation products should be more stable both toward oxygen and toward aromatization to pyrene. Studies on such derivatives are in progress.

## A Stereoselective Synthesis of Hydroazulenes. Grounds for Structure Revision of the Vetivane Sesquiterpenes

Sir:

With a view toward the total synthesis of  $\beta$ -vetivone, a constituent of the essential oil of vetiver,<sup>1</sup> we formulated a new stereoselective route to substituted hydroazulenes and thereby prepared the three 6,10-dimethyl-*cis*-decahydroazulen-8-ones 12a–c. In this report we describe these synthetic studies and show that none of the aforementioned hydroazulenones corresponds to either of the epimeric desisopropylidenedihydro- $\beta$ -vetivones prepared from  $\beta$ -vetivone. This finding invalidates not only the structure (I) heretofore accepted<sup>1,2</sup> for  $\beta$ -vetivone but, by virtue of reported chemical correlations, the proposed carbon framework (II) of the entire class of bicyclic vetivane sesquiterpenes as well.<sup>2c,3</sup>

Methylation (KO-*t*-Bu, CH<sub>3</sub>I)<sup>4</sup> of the known hydrindanone 1<sup>5</sup> afforded the dimethyl derivative 2 [ $\lambda_{\text{max}}^{\text{film}}$  3.28 (C=CH), 5.84 (CO), 6.09 (C=C), 8.78, 9.21, 9.58, 9.82, 9.92, and 10.05  $\mu$ ;  $\delta_{\text{TMS}}^{\text{CCl}_4}$  = 5.36 (H-3, four lines,  $J_{1,2}$  = 2 Hz,  $J_{3,7a}$  = 2 Hz), 1.21, and 1.20 ppm (C-4 dimethyl)]. This substance yielded principally the *cis*-hydrindanone 3a [ $\lambda_{\text{max}}^{\text{film}}$  5.86 (CO), 10.14, 10.86, and 11.59  $\mu$ , purified *via* the semicarbazone derivative, mp 207–208°] upon hydrogenation over palladium on carbon in ethanol. The minor hydrogenation product was identified as the *trans*-hydrindanone 3b by comparison with an authentic sample.<sup>6</sup> Bromination followed by dehydrobromination<sup>4</sup> converted hydrindanone 3a to the conjugated ketone 4 [ $\lambda_{\text{max}}^{\text{film}}$  5.96 (CO), 6.18 (C=C), 8.91, 10.82, 11.80, and 12.41  $\mu$ ]. Hydrogenation (Pd-C) regenerated the *cis*-hydrindanone 3a thus confirming our expectation<sup>4</sup> that isomerization of the ring fusion had not occurred en route to the conjugated ketone 4 (Chart I).

Addition of methylmagnesium iodide to hydrindanone 4 in the initial presence of cupric acetate<sup>4</sup> afforded the 1,4 adduct 5 [ $\lambda_{\text{max}}^{\text{film}}$  5.84 (CO), 8.90, 9.10, 9.63, and 9.95  $\mu$ ;  $\delta_{\text{TMS}}^{\text{CCl}_4}$  = 1.27, 0.97 (C-4 dimethyl, two singlets), and 1.01 ppm (C-7 methyl doublet,  $J$  = 5.0 Hz)]. This

stance yielded the corresponding conjugated ketone 12a upon bromination and subsequent dehydrobromination.<sup>4</sup> Expectedly, reduction of this conjugated ketone with lithium in ammonia<sup>7</sup> regenerated the saturated ketone 5, whereas hydrogenation (Pd-C in ethanol) gave ketone 7 [ $\lambda_{\text{max}}^{\text{film}}$  5.86 (CO), 8.90, 9.48, and 11.70  $\mu$ ;  $\delta_{\text{max}}^{\text{film}}$  = 1.15, 0.98 (C-4 dimethyl, two singlets), and 0.93  $\mu$  (C-7 methyl doublet,  $J$  = 5.7 Hz)], which readily afforded its conjugated ketone progenitor 6 upon bromination-dehydrobromination.<sup>4</sup>

Previous studies<sup>4</sup> provide a basis for the *a priori* assignment of stereochemistry to ketone 5. The spectroscopic properties of the  $\alpha$ -bromo ketones derived from 5

Cf. G. Stork and S. D. Darling, *J. Am. Chem. Soc.*, **86**, 1761 (1964).

and 7 support this assignment. Thus ketone 5 affords bromo derivatives 13a [mp 97–98°,  $\lambda_{\text{max}}^{\text{KBr}}$  5.81  $\mu$ ;  $\delta_{\text{TMS}}^{\text{CCl}_4}$  = 4.77 ppm (H-6 doublet,  $J_{6,7}$  = 11.2 Hz)], an equatorial  $\alpha$ -bromo ketone,<sup>4</sup> and 13b [ $\lambda_{\text{max}}^{\text{film}}$  5.86  $\mu$ ;  $\delta_{\text{TMS}}^{\text{CCl}_4}$  = 4.20 ppm (H-6 doublet,  $J_{6,7}$  = 2.4 Hz)], an axial  $\alpha$ -bromo ketone,<sup>4</sup> in the ratio 6:1 upon bromination in acetic acid. In contrast, ketone 7 yields only an equatorial bromo ketone 14 [ $\lambda_{\text{max}}^{\text{film}}$  5.81  $\mu$ ;  $\delta_{\text{TMS}}^{\text{CCl}_4}$  = 4.10 ppm (H-6 doublet,  $J_{6,7}$  = 12.2 Hz)] under these conditions.

We recently reported<sup>8</sup> the conversion of hydrindanone 5 to hydroazulenol 11a *via* fragmentation of the oxime derivative 8a (mp 150°) to nitrile 9a in pyridine containing *p*-toluenesulfonyl chloride, reduction of this nitrile with diisobutylaluminum hydride,<sup>9</sup> and cyclization of the resulting aldehyde 10a with stannic chloride in benzene. The epimeric hydrindanone 7 was transformed in a similar manner to the oxime 8b (mp 98°), nitrile 9b, aldehyde 10b, and hydroazulenol 11b [ $\lambda_{\text{max}}^{\text{film}}$  2.95 (OH), 3.25 (C=CH<sub>2</sub>), 6.11 (C=C), 9.45, 9.61, 9.75, 11.23 (C=CH<sub>2</sub>), 12.42, and 12.55  $\mu$ ]. Aldehyde 10b, like its methyl epimer 10a, afforded principally one isomer (95% according to the gas chromatogram) in the cyclization step.

Catalytic hydrogenation (Pt in ethanol) of unsaturated alcohol 11a afforded a mixture (*ca.* 1:1) of two dihydro compounds (methyl epimers) which, in turn, gave ketones 12a [ $\lambda_{\text{max}}^{\text{film}}$  5.88 (CO), 8.86, 9.12, 9.32, and 9.60  $\mu$ ] and 12b [ $\lambda_{\text{max}}^{\text{film}}$  5.88 (CO), 8.85, and 9.32  $\mu$ ], respectively, upon oxidation with chromic acid. Similar treatment of unsaturated alcohol 11b likewise afforded two ketones (in the ratio 40:60) of which the major component was identified by spectra comparison and gas chromatographic behavior (peak enhancement) as one of the ketones obtained from 11a. This substance must therefore possess *trans* oriented methyl groups as in 12b. The stereochemistry of the minor ketone 12c [ $\lambda_{\text{max}}^{\text{film}}$  5.90 (CO), 8.50, 8.70, 8.9, 9.21, and 9.34  $\mu$ ] follows from its hydrindanone precursor 7.

(-)- $\beta$ -Vetivone was secured from vetivert acetate, Java origin, and identified by its melting point,<sup>2a,b</sup> optical rotation,<sup>2a,b</sup> infrared spectrum,<sup>2e,10</sup> and nmr spectrum.<sup>2e</sup>

Following the hydrogenation-ozonolysis sequence reported by Pfau and Plattner,<sup>2a</sup> we converted (-)- $\beta$ -vetivone first to the *meso*-dihydro alcohol [a 65:35 mixture of alcohol epimers, mp 68–74°;  $\lambda_{\text{max}}^{\text{KBr}}$  3.1 (OH), 9.7, 10.40, 10.61, 10.93, and 12.61  $\mu$ ], and then to the desisopropylidene compound [ $\lambda_{\text{max}}^{\text{film}}$  2.94 (OH), 5.77 (CO), 9.74, 10.92, and 12.18  $\mu$ ]. The thioketal derivative of this hydroxy ketone afforded the alcohol upon desulfurization (H<sub>2</sub>, Raney nickel). Oxidation with chromic acid then gave the desired ketone, *meso*-desisopropylidenedihydro- $\beta$ -vetivone [ $\lambda_{\text{max}}^{\text{film}}$  5.81 (CO), 8.63, 8.75, 10.24, 10.72, and 11.67  $\mu$ ]. The infrared spectrum

(8) J. A. Marshall and N. H. Andersen, *Tetrahedron Letters*, 1219 (1967).

(9) Cf. L. I. Zakharkin and I. M. Khorlina, *Dokl. Akad. Nauk SSSR*, **116**, 422 (1957); *Chem. Abstr.*, **52**, 8040f (1958).

(10) J. C. Nigam and L. Levi, *Can. J. Chem.*, **40**, 2883 (1962).

of this substance clearly differed from that of its alleged synthetic counterpart 12a and the isomers thereof (12b and c).

Reduction of (-)- $\beta$ -vetivone with lithium in ammonia-ethanol afforded principally a new dihydro alcohol [40% yield,  $\lambda_{\text{max}}^{\text{film}}$  3.00 (OH), 9.71, 10.38, and 11.05  $\mu$ ] along with one of the previously obtained *meso* dihydro alcohols (15% yield) and recovered starting material. Degradation of this new dihydro alcohol along the lines described above for the *meso* compound afforded a new desisopropylidenedihydro- $\beta$ -vetivone [ $\lambda_{\text{max}}^{\text{film}}$  5.81 (CO), 8.64, and 9.6  $\mu$ ] whose infrared spectrum bore no close resemblance to that of its supposed racemic counterpart 12b or the synthetic *meso* compounds 12a and c.

In view of the nonidentity of our naturally derived and synthetic ketones we must conclude that  $\beta$ -vetivone cannot be represented by I or a stereoisomer thereof. Evidence which supports a spiro[4.5]decane skeleton for this substance and its relatives is presented in the following paper.

## The Structure of $\beta$ -Vetivone and Related Vetivane Sesquiterpenes

Sir:

The preceding report<sup>1</sup> summarizes synthetic and degradative work refuting the previously proposed structure (I) for  $\beta$ -vetivone<sup>2</sup> and those related sesquiterpenes whose carbon skeletons hinge on their correlation with "isovetivane" (II).<sup>3</sup> In this earlier work we noted

that the carbonyl absorption ( $\lambda_{\text{max}}$  5.81  $\mu$ ) of dihydro- $\beta$ -vetivone and desisopropylidenedihydro- $\beta$ -vetivone seemed better accommodated by a cyclohexanone than a cycloheptanone as previously formulated.<sup>1</sup> We therefore sought alternative structures for these substances based on cyclohexanone. With this in mind and after considering the wealth of chemical and physical data recorded for  $\beta$ -vetivone,<sup>1,2</sup> we decided on the spiro[4.5]decane III and IV as likely possibilities.

Chart I summarizes the transformations which v this proposal and allow us to choose III as the co structure.

Chart I

The known *meso*-dihydro- $\beta$ -vetivone (1)<sup>4</sup> yields corresponding unsaturated hydrocarbon 2 [ $\lambda_{\text{max}}^{\text{film}}$  8.71, 9.06, 9.46, 10.23, and 10.59  $\mu$ ;  $\delta_{\text{TMS}}^{\text{CCl}_4}$  = 1.60 (CH<sub>3</sub>), 1.25 (ring H envelope), and 0.80 ppm (CH doublet,  $J$  = 5 Hz)] upon Wolff-Kishner reduction of the semicarbazone derivative, mp 192–193°. onolysis<sup>4</sup> afforded the cyclopentanone 3 [ $\lambda_{\text{max}}^{\text{film}}$  (CO), 7.11, 7.24, 8.42, 8.61, 9.44, 10.60, and 11.2  $\mu$ ] which in turn gave the hydrocarbon 6 [ $\lambda_{\text{max}}^{\text{film}}$  7.24, 9.42, 10.29, 11.00, 11.10, and 11.20  $\mu$ ] after conversion to the ethylene thioketal derivative and desulfurization with W-2 Raney nickel<sup>5</sup> in refluxing ethanol.

We secured an authentic sample of the spiro[4.5]decane 6 from hydroxy ketone 4,<sup>7</sup> a known photochemical transformation product of *trans*-4a,8-dimethyl-5,6,7,8-tetrahydro-2(4aH)-naphthalenone. Dehydration with thionyl chloride in pyridine led to a mixture of olefins [ $\lambda_{\text{max}}^{\text{film}}$  5.75 (CO), 7.11, 7.24, 10.12, 10.25, 10.36, 11.06, 11.79, and 12.42  $\mu$ ], m 5 along with a minor amount of the exocyclic double bond isomer. Hydrogenation over palladium on carbon in ethanol afforded a mixture of ketones 8 [ $\lambda_{\text{max}}^{\text{film}}$  (CO), 7.11, 7.24, 8.53, 8.67, 10.20, 10.50, 10.60, and 11.25  $\mu$ ] and 9 [ $\lambda_{\text{max}}^{\text{film}}$  5.75, 7.11, 7.24, 8.53, 8.67, 10.20, 10.50, 10.60, and 11.25  $\mu$ ].

(7) P. J. Kropp and W. F. Erman, *J. Am. Chem. Soc.*, **85**, 181 (1963).

10.16, 10.48, 10.70, and 11.27  $\mu$ ] in the ratio 2:3 judged by the gas chromatogram. The major component of this mixture should be the *meso* isomer since the double bond in unsaturated ketone 5 appears from models to be somewhat hindered by the imate methyl group.<sup>8</sup> Ketones 8 and 9 differed by 3 according to the infrared spectra and gas chromatographic behavior. However, desulfurization of thioketal derivative of ketone 9 afforded the same monocarbon 6 previously obtained from  $\beta$ -vetivone. Ketones 8 and 9 must therefore be epimeric at the spiro junction. Ketone 8, when similarly treated, yielded hydrocarbon 7 [ $\lambda_{\text{max}}^{\text{film}}$  7.24, 8.63, 9.42, 10.25, 15, 10.95, and 11.33  $\mu$ ] which closely resembled these hydrocarbons could be cleanly separated by chromatography.

The above transformations require that  $\beta$ -vetivone be formulated as III, or the mirror image. The choice I can be made from Yosioka and Kimura's work in which hinesol (now formulated as V) was converted to  $\beta$ -vetivone (VI).<sup>9</sup> The absolute configuration of hinesol (V) follows from its degradation to (+)- $\alpha$ -

isovalerylglutaric acid by Šorm and co-workers.<sup>10</sup>

In view of the findings recorded above and in our previous report,<sup>1</sup> the list of sesquiterpenes containing a [4.5]decane ring system which previously contained the acrorones<sup>11</sup> and agarospirol<sup>12</sup> must now be extended to include  $\beta$ -vetivone, hinesol<sup>10</sup> (a close relative of agarospirol<sup>12</sup>), bicyclovetivenol,<sup>13</sup>  $\alpha$ -isovetivene, and  $\beta$ -isovetivenene.<sup>3</sup>

Kropp (Procter & Gamble Company, Cincinnati, Ohio) for a supply of tetrahydronaphthalenone.

This methyl group probably prefers an axial conformation to *gauche* butane interactions with the adjacent spiro methylenes. An orientation may be particularly favored with olefin 5 because the double bond alleviates or removes the unfavorable *gauche* interaction normally associated with an axial methylcyclohexane. Cf. ## The Acidities of Weak Acids in Dimethyl Sulfoxide (DMSO) Solutions. III. Comments on the *H*-Acidity Scales

Sir:

There has been some apparent disparity between the acidity scale in cyclohexylamine solvent developed by Streitwieser<sup>1</sup> and his co-workers and one which we reported earlier<sup>2</sup> for DMSO, aqueous DMSO, and methanolic DMSO. We present here some recent results which bring the two scales into better over-all agreement but which indicate a significant difficulty in basing the scales satisfactorily on the aqueous reference state.

In our previous communication<sup>2</sup> we reported a  $\Delta pK$  between fluorene (FH) and 9-phenylxanthene (PXH) of 3.7–3.8. Subsequent work showed that the actual  $\Delta pK$  was too great to relate the indicators directly, and an intermediate indicator, 1,1,3-triphenylpropene (TPH), has now been used. The result is that the  $pK$  of indicators less acidic than fluorene must be increased by about 1.6 units. This gives a  $pK$  span of 9.7 units between FH and our least acidic indicator, diphenylmethane (DH), as compared to Streitwieser's span of 10.4. This is surprisingly good agreement considering the vast difference in the acidities involved and the difference in solvent systems.

A second point of inconsistency is the assignment of absolute  $pK$  values. We based our scale on 4-nitroaniline (NAH), the  $pK$  of which was reported to be 18.4 by Stewart and O'Donnell,<sup>3</sup> a value based on the aqueous reference state. Streitwieser's scale is based on 9-phenylfluorene (PFH), the  $pK$  of which is reported to be 18.5 by Langford and Burwell<sup>4</sup> and 18.6 by Bowden and Stewart.<sup>5</sup> We have related FH to NAH, FH to PFH, and PFH to NAH, and find that PFH is significantly more acidic than previously reported. Ritchie has also found this to be the case.<sup>6</sup> With these results our  $\Delta pK$  between PFH and DH is 13.6 while Streitwieser's is 14.6—still excellent agreement. Furthermore, if both scales are based on the same reference compound the absolute  $pK$  values are within 1  $pK$  unit throughout.

Absolute  $pK$  values have been avoided intentionally in the above discussion. The reason is that large deviations have been found between the hydrocarbon indicators, PFH and FH, and the nitroanilines in aqueous DMSO, and this causes uncertainties in basing the acidity scale on the aqueous reference state. This is shown graphically in Figure 1 where the *H*- of 10 mM KOH solutions in aqueous DMSO is plotted against  $-\log [H_2O]$  using the different indicators. Values calculated from the data of Stewart, O'Donnell, and Dolman<sup>7</sup> are also included. They used  $Me_4N^+$  as the cation. The  $pK$  values of the nitroanilines are assumed to be those reported by Stewart and O'Donnell.<sup>3</sup>

Figure 1. Base strength of aqueous DMSO solutions as a function of water concentration:  $\circ$ , 2,4-dinitrodiphenylamine,  $[\text{KOH}] = 10 \text{ mM}$ ;  $\circ$ , 4-nitroaniline,  $[\text{KOH}] = 10 \text{ mM}$ ;  $*$ , calculated from data in ref 7,  $[\text{Me}_4\text{N}^+\text{OH}^-] = 11 \text{ mM}$  adjusted to  $10 \text{ mM}$ ;  $\circ$ , 9-phenylfluorene ( $pK = 18.1$  assumed),  $[\text{KOH}] = 10 \text{ mM}$ ;  $\bullet$ , fluorene ( $pK = 21.1$  assumed),  $[\text{KOH}] = 10 \text{ mM}$ .

The  $pK$ 's of PFH and FH are set at 18.1 and 21.1 so that  $H_-$  values measured with them conform to the aniline scale at the higher water concentrations. Clearly, the two types of indicators do not behave ideally relative to each other since the curves are not parallel. Furthermore, the  $\Delta pK$  between, say, NAH and PFH will depend strongly on solvent composition, and therefore a large uncertainty is inevitable when absolute  $pK$  values are assigned to the less acidic hydrocarbons. This same sort of discrepancy obtains also in methanolic DMSO, although it is not as serious. The discrepancy is negligible in ethanolic DMSO.

The causes of the deviations have not been investigated, but it seems likely that the nitro groups are an important factor. Thus if the anion of 4-nitroaniline is stabilized by hydrogen bonding to water, an increase

in water concentration would increase the acidity of NAH relative to that of PFH, as is observed. Salting out of the un-ionized hydrocarbon by water, another possible source of nonideality, should have an effect opposite to that observed. It is interesting to note that  $H_-$  data measured in methanolic DMSO with 4-nitrotriphenylmethane and with bis(4-nitrobenzyl) sulfone<sup>8</sup> parallel very closely the data from the nitroanilines.

At the present time it appears to us that the nitroaniline scale is the most firmly anchored in the aqueous reference state. Furthermore, it is fairly consistent in a number of aqueous and alcoholic DMSO solutions as well as in pure DMSO. As such, it can be a useful tool. The nonideality between the anilines and the

(8) Measured in our laboratory by R. H. Imes in cooperation with Dr. F. G. Bordwell.

more acidic hydrocarbons creates large uncertainties in the  $pK$  values assigned to the hydrocarbons, but since the aniline scale is the only available link between the hydrocarbons and the aqueous reference state there is little choice but to use it temporarily as the base for the hydrocarbons. If the hydrocarbon scale can be satisfactorily related directly to the  $pH$  scale, then perhaps a more valid and widely applicable  $H_-$  scale can be developed. A more detailed description of the  $H_-$  scale in a number of alcoholic DMSO mixtures will be given in a subsequent communication.

## Acidity in Nonaqueous Solvents. V. Acidity Scales in Dimethyl Sulfoxide Solution<sup>1,2</sup>

Sir:

Using the potentiometric method recently described,<sup>3</sup> we have determined the "absolute"<sup>4</sup> acidities of several additional carbon acids in dimethyl sulfoxide solution. The new data, presented in Table I, along with some pertinent previously reported data, provide an explanation of major discrepancies between reported relative acidities in dimethyl sulfoxide and cyclohexylamine solution<sup>4</sup> and provide further insight into the nature of the effect of changing solvent on the relative acidities of various acids.

Table I. Comparison of Acidities in Various Solvents

Acid	$pK(\text{DMSO})^a$	$pK(\text{H}_2\text{O})^b$	$pK(\text{CHA})^c$
9-Carbomethoxyfluorene	10.3	12.9 <sup>d,e</sup>	...
<i>p</i> -Nitrophenol	10.4 <sup>f</sup>	7.1	...
Acetic acid	11.6 <sup>f</sup>	4.8	...
Malononitrile	11.0	11.1 <sup>d,e</sup>	...
Benzoylacetone	12.1 <sup>f</sup>	9.6	...
Tris( <i>p</i> -nitrophenyl)-methane	12.2 <sup>f</sup>	14.3 <sup>d,e</sup>	...
Acetylacetone	13.4	9.0	...
2,4-Dinitroaniline	14.8 <sup>f</sup>	14.7 <sup>d</sup>	...
Nitromethane	15.9 <sup>f</sup>	10.2	...
9-Phenylfluorene	16.4	18.6 <sup>d,e</sup>	(16.4)
Indene	18.5	18.2 <sup>d</sup>	17.8
9-Methylfluorene	19.7 <sup>f</sup>	...	...
4,5-Methylenephene-anthrene	20.0	...	20.5
Fluorene	20.5	20.5 <sup>d</sup>	20.6
Triphenylmethane	~28	28.8 <sup>d,A</sup>	29.4

<sup>a</sup> Standard state in dimethyl sulfoxide solution. Estimated accuracy:  $\pm 0.3$   $pK$  unit (see ref 2). All measurements at  $25.0^\circ$ .

<sup>b</sup> Those values not referenced were actually determined in aqueous solution. Others have been determined by acidity function techniques. <sup>c</sup> Values taken from ref 4 and adjusted to  $pK = 16.4$  for 9-phenylfluorene. <sup>d</sup> Values determined by acidity function techniques. <sup>e</sup> From ref 5. <sup>f</sup> Values from ref 2. <sup>g</sup> Value determined in aqueous solution and used as the standard for establishment of an  $H_-$  scale. See ref 5. <sup>A</sup> Personal communication from Dr. E. C. Steiner.

(1) This work was supported by Grant No. GM 12832 from the Public Health Service, National Institutes of Health.

(2) For previous papers in this series, see: C. D. Ritchie and R. E. Uchold, *J. Am. Chem. Soc.*, **89**, 1721 (1967), and earlier references cited there.

(3) The word "absolute" is used in the sense that the equilibrium constants are referred to a standard state in the solvent in which they are measured.

(4) A. Streitwieser, Jr., E. Ciuffarin, and J. H. Hammons, *J. Am. Chem. Soc.*, **89**, 63 (1967).

value of 11.14 for malononitrile in aqueous was determined by Bowden and Stewart.<sup>5</sup> was then used as the "anchor compound" in an acidity scale in ethanol-dimethyl sulfoxides. The scale was applied to the measured  $K$  values for a number of carbon acids, among them 9-carbomethoxyfluorene, tris(*p*-nitrophenyl)- and 9-phenylfluorene. The  $pK(H_2O)$  values in the table for these compounds are those of Bowden and Stewart.

Present data clearly show the breakdown of the scale. The relative acidity of malononitrile and 9-carbomethoxyfluorene changes by 2.5  $pK$  units on going from ethanol to dimethyl sulfoxide solution. The relative acidities of 9-carbomethoxyfluorene and either *o*-phenylmethane or 9-phenylfluorene, however, are nearly the same in both determinations.

It appears probable that the agreement reported<sup>2</sup> between our "absolute"  $pK$ 's and those determined by Steiner<sup>6</sup> by acidity function technique is purely fortuitous. Apparently, the reference acid, 4-nitroaniline, used by Steiner for determining the other acids just happens to be one for which  $pK$  is not strongly affected by the change of solvent. Malononitrile appears to be another such acid, showing the same  $pK$  in water and dimethyl

sulfoxide as discussed in our previous paper,<sup>2</sup> four distinct effects are expected to influence the change in acidity on going from water to dimethyl sulfoxide. These effects, the greater basicity of dimethyl sulfoxide than water and the dispersion interaction of colored anions with solvent, would act to increase acidity in dimethyl sulfoxide. The other two electrostatic effects and hydrogen bonding of the conjugate base, would decrease acidity in dimethyl sulfoxide. For the nitroanilines and for malononitrile it appears that these effects just balance. We believe that this cancellation is purely fortuitous. The results from different magnitudes of the effects in the two cases. Both hydrogen bonding and the dispersion interactions are expected to be stronger for the nitroanilines than for malononitrile. The increase in acidity of 9-carbomethoxyfluorene relative to malononitrile in going from ethanol to dimethyl sulfoxide is most reasonably attributed to the net interactions of the substituted fluorenyl anion with the polarizable solvent.

Conclusions pertinent to current investigations of acidities of hydrocarbons can be drawn from the present data. First, and in our opinion most important, the data clearly show that no single Hammett function applicable to acids of different structures can be constructed to reach into pure dimethyl sulfoxide. This conclusion is further strengthened by the results of Steiner's recent study.<sup>7</sup>

Second, if the relative acidities of various hydrocarbons in cyclohexylamine solution, determined by Steiner,<sup>4</sup> are adjusted to our value of 16.4 for the 9-phenylfluorene, rather than to the previously

used value of 18.5, the discrepancies noted between the scales in dimethyl sulfoxide and cyclohexylamine solutions no longer appear, and, in fact, the agreement, as shown in Table I, is even better than might have been expected for two such different solvents.

### A Novel Method for the Synthesis of Isomerically Pure Vinyl Halides from Alkynes via the Hydroalumination Reaction<sup>1</sup>

Sir:

The addition of bromine to vinylorganoboranes results in the formation of 1,2-dibromoboranes. These derivatives are converted to vinyl halides when treated with water or aqueous sodium hydroxide.<sup>2</sup> Recently, Matteson and Liedtke<sup>3</sup> have suggested that bromine adds *trans* to unsaturated boronic esters, and they have established that deboronobromination involves a stereospecific *trans* elimination. In concurrence with these results is the observation by Brown<sup>4</sup> that bromination of *trans*-1-hex-1-enyl-bis(3-methyl-2-butyl)borane, derived from hydroboration of 1-hexyne with bis(3-methyl-2-butyl)borane,<sup>4</sup> gives after hydrolysis *cis*-1-bromo-1-hexene.

We have now investigated the halogenation of vinylalanes. These derivatives are readily available by hydroalumination of alkynes with diisobutylaluminum hydride in a hydrocarbon solvent.<sup>5</sup> This involves a *cis* addition of the aluminum-hydrogen bond to the triple bond, yielding *trans*-vinylalanes from 1-alkynes and *cis*-vinylalanes from disubstituted alkynes. Treatment of the *trans*-vinylalane derived from 1-hexyne in tetrahydrofuran with various halogens in a 1:1 ratio at  $-50^\circ$  produces essentially pure *trans*-1-halo-1-hexenes. Under similar experimental conditions the *cis*-vinylalane obtained from 3-hexyne reacts with bromine or iodine to give the corresponding *cis*-3-halo-3-hexenes. The experimental results are summarized in Table I.

The fact that halogenation of unsaturated alanes proceeds with retention of configuration supports the contention that vinylalanes undergo electrophilic cleavage (1) preferentially at the vinyl carbon-aluminum bond. Formation of vinyl halides from vinylboranes, however, is the result of an addition-elimination reaction (2). It should be noted that the reaction of chlorine with the vinylalane derived from 1-hexyne gives a 70:30 mixture of *trans*- and *cis*-1-chloro-1-hexene, indicating a competition between addition to the double bond and cleavage at the vinyl carbon-aluminum bond.

<sup>a</sup> Both bromine and iodine monochloride were dissolved in methylene chloride and then added to the vinylalane. Iodine was used in tetrahydrofuran. <sup>b</sup> Analysis by glpc with an internal standard. <sup>c</sup> The assignments for the vinyl halides are based on infrared and nmr data. <sup>d</sup> *trans*-1-Iodo-1-hexene.

With increasing reactivity of the halogen, there is less discrimination between cleavages at the hexenyl-aluminum and isobutyl-aluminum bonds. In these cases the vinyl halide is contaminated with the isobutyl halide. In order to maximize the yield of the vinyl halide, larger amounts of halogens should be used.

The simplicity of this procedure makes it a valuable method for synthesis of isomerically pure vinyl halides. The isobutyl groups on aluminum do not interfere with the isolation of the halides since they are converted to isobutane in the hydrolysis step. It is of special importance in that 1-iodo-1-alkenes, which cannot be prepared by the addition of hydrogen iodide to 1-alkynes in the presence of peroxides, are obtained in excellent yield from the corresponding vinylalanes. A representative procedure is given below.

To 0.10 mole of 1-hexyne in 20 ml of *n*-heptane was added 0.10 mole of diisobutylaluminum hydride while maintaining the temperature below 40°. When the initial exothermic reaction had subsided, the reaction mixture was heated for 2 hr at 50°. The heptane was then removed under reduced pressure (0.5 mm), and the residue obtained was diluted with 40 ml of tetrahydrofuran. To this vinylalane solution at -50° was added 0.10 mole of iodine in 40 ml of tetrahydrofuran. After allowing the reaction mixture to warm up to room temperature, the diisobutylalane (-Al(C<sub>4</sub>H<sub>9</sub>)<sub>2</sub>) was decomposed at 20-30° by dropwise addition of 20% sulfuric acid (exothermic reaction). When the isobutane evolution had diminished, the reaction mixture was poured into ice-20% H<sub>2</sub>SO<sub>4</sub>. The vinyl iodide was extracted into pentane and the combined extracts were washed first with sodium thiosulfate, then with sodium bicarbonate. Distillation gave 15.52 g of *trans*-1-iodo-1-hexene (74%); bp 50-52° (3 mm), *n*<sub>D</sub><sup>20</sup> 1.5072. A small amount of the vinyl iodide was converted to the vinyl-lithium derivative,<sup>6</sup> which was hydrolyzed with deuterium oxide. The infrared and nmr spectra of the

### A New and Convenient Method for the Preparation of Isomerically Pure $\alpha,\beta$ -Unsaturated Derivatives via Hydroalumination of Alkynes

Sir:

Relatively little attention has been directed to the utilization of organoalanes as Grignard-like reagents. Ziegler and co-workers<sup>1</sup> have shown that the addition of carbon dioxide to trialkylalanes at atmospheric pressure and at room temperature in hydrocarbon solvents results in the carbonation of only one carbon-aluminum bond. Similarly, we have observed that carbonation of vinylalanes in hydrocarbon solvents affords the corresponding  $\alpha,\beta$ -unsaturated acids in modest yields (30-37%). Both trialkylalanes and vinylalanes, however, fail to react with carbon dioxide in ether or hydrocarbon-ether mixtures at room temperature.

We now wish to report that the *ate* complexes of vinylalanes may be utilized for Grignard-type reactions. The required vinylalanes are readily accessible via hydroalumination of alkynes with diisobutylaluminum hydride in hydrocarbon solvents.<sup>2,3</sup> This involves a *cis* addition of the aluminum-hydrogen bond to the triple bond, yielding *trans*-vinylalanes from 1-alkynes and *cis*-vinylalanes from disubstituted alkynes. Treatment of the hydrocarbon solutions of vinylalanes with methyllithium in ether in a 1:1 ratio followed by carbonation gives the corresponding carboxylic acids in excellent yields. Likewise, acetaldehyde and para-

formaldehyde<sup>4</sup> may be treated with the *ate* complexes at 25 and 35°, respectively, to yield  $\alpha,\beta$ -unsaturated alcohols. A summary of the experimental results of these reactions is given in Table I.

Examination of the reaction mixtures by glpc revealed that the products obtained in each case were isomerically pure. Consequently, the reactions of vinylalanes with Grignard co-reagents proceed with retention of configuration. It was also noted that carbonation occurs exclusively at the vinyl-aluminum bond. The isobutyl moieties of the hydroaluminating agent are converted to isobutane in the hydrolysis step, and hence do not interfere in the isolation of the products.

solution. <sup>a</sup> Yields are based on the amount of alkyne used.  
maldehyde. <sup>d</sup> Yield 90% by glpc analysis.

ough the nature of the reactive organometallic  
mediates has not been established, it is conceivable  
the reactions proceed *via* the vinylolithium deriva-  
resulting from disproportionation of the vinyl-  
s. The configurational stability of vinylolithium

unds in solution, a requirement in view of the  
tereospecificity of the above reactions, has been  
strated by Seyferth and co-workers.<sup>5</sup> We have  
ed that tetraalkylalanes do not react with  
dioxide; however, their disproportionation  
kylolithium compounds and trialkylalanes should  
modynamically unfavorable.

ynthesis of vinylalanes is not confined to the  
lumination reaction. Thus trialkylalanes add  
ethylene under mild conditions to yield *cis*-vinyl-  
whereas addition of the aluminum-carbon bond  
alkynes affords the corresponding disubstituted  
anes.<sup>3</sup> The availability of *cis*- and *trans*-mono-

uted vinylalanes greatly increases the versatility  
above reactions.

simplicity of the present procedure for the con-  
1 of alkynes into  $\alpha,\beta$ -unsaturated derivatives  
ylalanes is illustrated by the following example.  
0.10 mole of 1-hexyne in 20 ml of *n*-heptane was  
by means of a hypodermic syringe 0.10 mole of  
ethylaluminum hydride, while maintaining the  
perature below 40°. After the initial exothermic  
m had subsided, the reaction mixture was heated  
ir at 50°. To the vinylalane formed was added at  
temperature 0.10 mole of methylolithium in ether  
l). The solution was cooled to -30°, then car-  
ed by introducing a stream of carbon dioxide  
maintaining the temperature at -30 to -10°. The  
reaction mixture was poured slowly into an ice-  
strated hydrochloric acid mixture and the car-  
c acid produced was extracted into ether. Distil-

 Organonickel Compounds as Reagents for Selective  
Carbon-Carbon Bond Formation between Unlike Groups

Sir:

The extension of carbon chains by the coupling of  
two different groups using as reagents an organic halide,  
RHal, and an alkyl- or arylmetal derivative, R'Met, is  
seldom employed in synthetic practice if alternative  
operations are available. This is due in part to the  
fact that coupling products RR and R'R' are usually  
formed in substantial amounts<sup>1</sup> and in part to the  
intervention of a variety of other side reactions, *e.g.*,  
 $\alpha$ - or  $\beta$ -elimination processes. We report here a new  
and promising method for the *selective combination of*  
*unlike groups* at carbon using organonickel reagents.

Reaction of a variety of allylic bromides with excess  
nickel carbonyl in dry benzene (50°, 2-3 hr) followed by  
removal of solvent and recrystallization from ether at  
-70°<sup>2</sup> gives good yields of  $\pi$ -allylnickel(I) bromides,  
for example, 1a-c, in 80-95% yield.<sup>3,4</sup> These complexes  
are relatively inert toward alkyl halides in either hydro-

carbon solvents or ether-type solvents (*e.g.*, tetrahydro-  
furan). In more *polar, coordinating media*, *e.g.*, di-  
methylformamide, N-methylpyrrolidone, or hexa-  
methylphosphoramide, a facile reaction occurs between  
the complexes 1 and a *wide variety* of halides, with  
iodides generally being more reactive than (and pre-  
ferable to) bromides.<sup>5</sup> Equation 1 summarizes the  
over-all reaction, and Table I presents the results ob-

(1) For example, because of fast halogen-metal exchange prior to  
coupling. See D. E. Applequist and D. F. O'Brien, *J. Am. Chem. Soc.*,  
85, 743 (1963).

(2) All operations with organonickel compounds have been con-  
ducted with rigorous exclusion of oxygen using an argon atmosphere  
either with plastic glove bag or argon-line techniques.

(3) The complex 1a, first prepared by E. O. Fischer and G. Bürger,  
*Z. Naturforsch.*, 16b, 77 (1961), was originally obtained only in *ca.*  
10% yield; however, much higher yields are easily realized if thermal  
or oxidative decomposition of the complexes is avoided.

(4) These complexes can also be obtained efficiently from allylic  
bromides using bis(1,5-cyclooctadiene)nickel as reagent; see G. Wilke  
*et al.*, *Angew. Chem. Intern. Ed. Engl.*, 5, 159 (1966). However, the  
synthesis from commercially available nickel carbonyl is usually more  
expedient.

(5) Chlorides are less generally useful because of their much lower  
reactivity.

**Table I.** Coupling of  $\pi$ -Methallylnickel(I) Bromide (1b) with Halides (Eq 1) in Dimethylformamide

Halide	Reaction time, hr (temp, °C)	Yield, %
Methyl iodide	10 (22)	90 <sup>a</sup>
Methyl bromide	19 (22)	90 <sup>a</sup>
Cyclohexyl iodide	3 (22)	91
4-Hydroxycyclohexyl iodide	10 (22)	88 <sup>b</sup>
<i>t</i> -Butyl iodide	24 (22)	25 <sup>a</sup>
Iodobenzene	1 (22)	98
Vinyl bromide	13 (22)	70 <sup>a</sup>
Benzyl bromide	6 (60)	91
3-Phenylpropyl bromide	46 (65)	92
Phenyl $\alpha$ -chloromethyl ether	18 (60)	50
<i>p</i> -Bromophenacyl bromide	0.5 (22)	75
Chloroacetone	2 (22)	46 <sup>a</sup>

<sup>a</sup> These yields were determined by quantitative vpc analysis; others are yields of isolated pure products. <sup>b</sup> Mixture of *cis* and *trans* isomers which are converted by chromic acid oxidation to 4-methylcyclohexanone.

tained with 1b and a diverse collection of substrates.<sup>6</sup> The reaction proceeds well not only with alkyl iodides and bromides but also with *aryl* and *vinyl* compounds. Further, the data indicate that the presence of carbonyl or hydroxyl functions in the halide partner need not interfere with coupling. Dihalides undergo disubstitution with the appropriate quantity of nickel(I) complex, as shown by the conversion of 1,6-diiodohexane with 1b (mole ratio 1:1.25) to 2,11-dimethyl-1,11-dodecadiene (95% yield) and of 1,4-dibromobenzene with 1b (mole ratio 1:1.25) to 1,4-dimethallylbenzene (97%). The latter substance is not readily accessible by conventional synthetic methods.

The new method has been employed in direct and efficient syntheses of  $\alpha$ -santalene (2)<sup>7</sup> (88% yield) and *epi*- $\beta$ -santalene (3)<sup>8</sup> (90% yield) using the nickel(I) complex from  $\alpha,\alpha$ -dimethylallyl bromide as follows.<sup>9</sup>

(6) The structures and products obtained by the reactions described herein have been verified by infrared, nmr, and mass spectrometric or elemental analysis. Purity was checked by vapor phase chromatography and quantitative nmr analysis.

(7) E. J. Corey, S. W. Chow, and R. A. Scherrer, *J. Am. Chem. Soc.*, **79**, 5773 (1957).

(8) E. J. Corey, R. Hartmann, and P. A. Vatakencherry, *ibid.*, **84**, 2611 (1962). The iodocamphene used in the synthesis of 3 was prepared from the corresponding bromide by successive treatment with magnesium, mercuric chloride, and iodine. The bromocamphene was derived from  $\pi$ -bromocamphor by reduction (BH<sub>4</sub><sup>-</sup>) and dehydration with POCl<sub>3</sub>-pyridine.

(9) The nickel(I)  $\pi$  complex from  $\alpha,\alpha$ -dimethylallyl bromide generally undergoes preferential coupling at the primary rather than at the

Substances of utility for further chain extension or cyclization can also be produced, for instance

In cases where substitution at C<sub>1</sub> and/or C<sub>3</sub> of the allyl group allows the possibility of geometrically isomeric coupling products, both *cis* and *trans* isomers usually result. For example, the  $\pi$  complex prepared from *trans*-geranyl bromide and nickel carbonyl affords with cyclohexyl iodide the coupling product 4 as a mixture of *cis-trans* isomers (40 and 60%).<sup>10</sup>

$\pi$ -Allylnickel(I) complexes also can react with substances other than halides. The methallyl complex 1b reacts with benzaldehyde, acrolein, and cyclopentanone in dimethylformamide to yield 5, R = C<sub>6</sub>H<sub>5</sub> (85%), 5, R = CH=CH<sub>2</sub> (80%), and 6 (50%), respectively, and styrene oxide affords 7 (60%). In general, these reactions are considerably slower than those of 1b with iodides, and more drastic conditions were used (50°, ca. 24 hr).

The more general problem of effecting cross-coupling reactions of unlike *nonallylic* groups is currently the subject of a parallel investigation in this laboratory, not only in the nickel series but also with other transition metal derivatives, for example, organocopper<sup>11-13</sup> and organosilver<sup>14-17</sup> compounds.

An especially crucial part of the coupling process described above is the step in which the new carbon-carbon bond is formed and in particular the precursor for that step. Among the possibilities which presently appear as reasonable is the complex 8 which might be formed, for example, by the route<sup>18</sup>

tertiary terminal; with methyl iodide it affords pure 2-methyl-2-pentene (by vpc and nmr analysis) in ca. 90% yield.

(10) The interconversion of *cis-trans* forms of the allyl group could occur within the nickel complexes, e.g., via reversible  $\sigma$ - $\pi$  bonding changes. See (a) J. Powell, S. D. Robinson, and B. L. Shaw, *Chem. Commun.*, 78 (1965); (b) K. G. Ramey and G. L. Statton, *J. Am. Chem. Soc.*, **88**, 4387 (1966). Alternatively, isomerization may involve equilibration of primary and tertiary allylic bromides via nickel(I)  $\sigma$  and  $\pi$  complexes.

(11) H. Gilman and J. M. Straley, *Rec. Trav. Chim.*, **55**, 821 (1936).

(12) R. G. R. Bacon and H. A. O. Hill, *Quart. Rev. (London)*, **19**, 95 (1965).

(13) C. E. Castro, *et al.*, *J. Org. Chem.*, **28**, 2163, 3313 (1963); **31**, 4071 (1966).

(14) E. A. Bickley and J. H. Gardner, *ibid.*, **5**, 126 (1940).

(15) G. M. Whitesides and C. P. Casey, *J. Am. Chem. Soc.*, **88**, 4541 (1966).

(17) H. C. Brown and C. H. Snyder, *J. Am. Chem. Soc.*, **83**, 1002 (1961).

(18) Experiments in progress have shown that bis- $\pi$ -allylnickel(0) is unreactive toward bromobenzene and less reactive toward cyclohexyl iodide than is  $\pi$ -allylnickel(I) bromide (unpublished work with L. S. Hegedus and H. A. Kirst). Consequently, 8 is considered a more likely intermediate than analogs which are derived from reaction of nickel(0) complexes with RX.

L = e.g., DMF

behavior of allylic halides toward  $\pi$ -allylnickel(I) complexes, which contrasts sharply with that of non-allylic halides such as those appearing in Table I, is detailed in due course.<sup>19</sup>

### Synthesis of Large-Ring 1,5-Dienes by Cyclization of Allylic Dibromides with Nickel Carbonyl

A method for forming cycloolefins from allylic dibromides and nickel carbonyl which has recently been described<sup>1,2</sup> has now been examined in order to ascertain its scope with a series of dibromides of structure 1. Results which have been obtained suggest that this

cyclization process provides an unusually efficient route to the formation of large rings. In addition, because of the wide variety of cyclic 1,5-dienes, it makes available a wide variety of cyclic structures which are not obtainable in any other way *via* the acyloin reaction, currently the most commonly used general approach to large rings. Allylic dibromides 1,  $n = 2, 4, 6, 8$ , and 12, were cyclized in both *cis,cis* and *trans,trans* forms from the corresponding diols 2,  $n = 2, 4, 6, 8$ , and 12, by selective cyclization to the corresponding *cis,cis*-<sup>3</sup> or *trans,trans*-ethylenic<sup>4</sup> diols<sup>5</sup> followed by reaction with phosphorus tribromide.<sup>6</sup> The required acetylenic diols  $n = 4, 6$ , and 8, were made by alkylation of a diolide,  $\text{Br}(\text{CH}_2)_n\text{Br}$ , with the sodio derivative of ethyl alcohol tetrahydropyranyl ether<sup>7</sup> in liquid ammonia-ether<sup>8</sup> ( $n = 4, 6, 8$ ) or in tetrahydrofuran-

Using Lindlar catalyst; see H. Lindlar and R. Dubuis, *Org. Syn.*, **46**, 1 (1966).

Using lithium aluminum hydride in tetrahydrofuran; see K. R. Weale and B. C. L. Weedon, *J. Chem. Soc.*, 1584 (1953).

Satisfactory analytical and spectroscopic (infrared and nmr) data have been obtained for the new compounds reported herein. Stereochemical assignments to the *cis,cis*- and *trans,trans*-dibromides have been made on the basis of the methods of synthesis (usually shown to be stereospecific) but also on the occurrence of absorption at 10.4 or 10.3  $\mu$  for the *trans,trans*-dihalides or at 13.1–13.4  $\mu$  for all the *cis,cis*-dibromides.

dimethyl sulfoxide ( $n = 12$ ), and the diol 2,  $n = 2$ , was obtained from 1,5-hexadiyne<sup>9</sup> and formaldehyde.<sup>10</sup>

The cyclization experiments were conducted by slow addition (motor-driven syringe, 12-hr period of addition) of the allylic dibromide (1 mmole) in dimethylformamide (1 ml) to a solution of nickel carbonyl (5 mmoles) in dimethylformamide (*ca.* 40 ml) under argon at 50°. In the cases of the dibromides 1,  $n = 6, 8$ , and 12, the same cyclization product was obtained starting with either *cis,cis* or *trans,trans* isomer.

In each of these cases the cyclization product was principally (95–98%) the *trans,trans*-1,5-diene, but small amounts of an isomeric compound, probably the *cis,trans* isomer, could be detected by vapor phase chromatography.<sup>11</sup> The major product from 1,  $n = 6$ , was identified as *trans,trans*-1,5-cyclododecadiene by spectroscopic comparison with the known substance;<sup>12</sup> the infrared spectrum manifested absorption at 10.4  $\mu$  due to  $\text{CH}=\text{CH}$  (*trans*) and no absorption at *ca.* 14.2  $\mu$  which would be expected for  $\text{CH}=\text{CH}$  (*cis*), and hydrogenation afforded cyclododecane, identical with an authentic sample. The principal products from 1,  $n = 8$ , and 1,  $n = 12$ , were identified by their infrared spectra (e.g., absorption at 10.4  $\mu$  but not at 14.2  $\mu$ ), mass spectra, nmr spectra, and hydrogenation to cyclo-tetradecane, mp 54–55°,<sup>13</sup> and cyclooctadecane, mp 71–72°,<sup>14</sup> respectively. The predominant course of cyclization with the dibromides 1,  $n = 2$ , and 1,  $n = 4$ , was formation of six-membered ring structures by 1–6 and 3–8 coupling, respectively; again the product composition was essentially independent of the geometry of the starting dibromide. With nickel carbonyl, 1,  $n = 2$ , afforded 4-vinylcyclohexene (42%) and *cis,cis*-1,5-cyclooctadiene (5%); the same products were also obtained using triphenylphosphinenickel tricarbonyl,<sup>14</sup> but the relative amount of 1,5-cyclooctadiene was somewhat greater (*ca.* 20% of the mixture). In the case of dibromide 1,  $n = 4$ , with either nickel carbonyl or triphenylphosphinenickel tricarbonyl, only

(14) See ref 2 for an example of ligand control of product using this reagent.

*cis*- and *trans*-1,2-divinylcyclohexane<sup>15</sup> were observed, with the former reagent giving a preponderance of the *cis* isomer and the latter favoring the *trans* isomer with a ratio of *ca.* 1:2; no 1,5-cyclodecadiene<sup>15,16</sup> could be detected spectroscopically or by vpc.

Although it has not yet been shown experimentally that the cyclization of allylic dibromides by nickel carbonyl can be used for the synthesis of ring sizes larger than 18, the efficiency of cyclization in the 18-membered case strongly suggests that it can.<sup>17</sup> The formation of essentially the same cyclization product from *cis-trans* isomeric dibromides is not surprising in view of earlier findings and similar results in intermolecular coupling reactions,<sup>18</sup> and it can be explained simply by allylic isomerization either because of allylic halogen-nickel exchange<sup>18</sup> or allylic rearrangement within the organonickel complexes *via*  $\sigma$ -allylnickel structures.<sup>19</sup>

The fact that the cyclization of 1, *n* = 2 and 4, leads mainly to six-membered ring structures indicates that the formation of this ring size relative to the alternative eight- and ten-membered structures is sufficiently favorable to overcome the marked preference for the joining of primary over secondary over tertiary carbons in allylic coupling.<sup>18,20,21</sup>

It is noteworthy that the efficiency of cyclization of the substrates 1, *n* = 2, 4, 6, 8, and 12, is strongly dependent on the solvent which is used; solvents such as dimethylformamide and N-methylpyrrolidone are much superior to, *e.g.*, tetrahydrofuran or glyme solvents. A discussion of these effects and detailed considerations of the mechanism of the cyclization process will be presented in due course.

It is apparent that the cyclization discussed herein is a very useful synthetic method. In principle it is applicable, for example, to a synthesis of elemol,<sup>22</sup>  $\beta$ -maaliene,<sup>23</sup> or cembrene.<sup>24</sup> A total synthesis of humulene has already been accomplished using this method.<sup>25,26</sup>

(15) Authentic samples of *cis*-1,2-divinylcyclohexane and *cis,trans*-1,5-cyclodecadiene were kindly provided by Dr. P. Heimbach, Max-Planck Institut, Mülheim, Germany; see P. Heimbach, *Angew. Chem. Intern. Ed. Engl.*, **3**, 702 (1964); **5**, 595 (1966).

(16) It was shown by a control experiment that *cis,trans*-1,5-cyclodecadiene was recovered unchanged after being subjected to cyclization conditions.

(17) A study of the cyclization of 1,40-dibromo-2,38-tetracontadiene which could give a 40-membered ring is now under way. The yields given for the cyclization of 1, *n* = 6, 8, 12, are probably not optimal, since only one set of reaction conditions was tried.

(18) E. J. Corey and M. F. Semmelhack, to be published.

(19) The intervention of allylnickel(I) bromide complexes in these cyclizations is clear from the development of the deep red color characteristic of such complexes during reaction. This color develops rapidly as the addition of dibromide to nickel carbonyl is started, and at the end of the addition it fades and gives way to the characteristic green color of nickel(II) bromide in dimethylformamide solution.

## Total Synthesis of Humulene

Sir:

We describe herein a total synthesis of humulene, 7 (2,6,6,9-tetramethyl-*trans,trans,trans*-cycloundeca-1,4,8-triene),<sup>1-4</sup> a fundamental monocyclic triisoprenoid structure which is a likely precursor of a number of other naturally occurring sesquiterpenes.<sup>5</sup> The key step in the synthesis is formation of the 11-membered ring by cyclization of a 1,11-dibromo-2,5,9-undecatriene derivative using nickel carbonyl.<sup>6</sup>

One important intermediate in the synthesis is the phosphonium ylide 1 which was obtained starting with dimethyl *trans*-3-methylglutaconate<sup>7</sup> by a sequence involving (1) reduction to the corresponding diol (2, U = V = OH) using lithium aluminum hydride-aluminum chloride (3:1)<sup>8</sup> in ether; (2) conversion to the dibromide 2, U = V = Br,<sup>9</sup> then selective displacement of the allylic bromine with trimethylbenzylammonium dichloroacetate in acetone to give 2, U = Br, V = OCOCHCl<sub>2</sub>; (3) basic hydrolysis to the bromohydrin 2, U = Br, V = OH; (4) acid-catalyzed addition to dihydropyran to form 2, U = Br, V = OTHP (THP = 2-tetrahydropyranyl ether), and (5) reaction with triphenylphosphine in acetonitrile at 80° for 24 hr to form the phosphonium (bromide), U = P<sup>+</sup>(C<sub>6</sub>H<sub>5</sub>)<sub>3</sub>, V = OTHP.

A second key intermediate is the aldehyde 3, the synthesis of which proceeded from 1-chloro-2-methyl-4-acetoxy-2-butene,<sup>10</sup> 4, W = Cl, X = OAc, as follows: (1) displacement of chloride from 4, W = Cl, X = OAc, by trimethylbenzylammonium mesitoate in ethanol at 80° for 24 hr to form 4, W = mesitoxyloxy, X = OAc; (2) selective alkaline hydrolysis to 4, W = mesitoxyloxy, X = OH; and (3) reaction with phosphorus tribromide<sup>11</sup> in ether to give 4, W = mesitoxyloxy, X = Br, which was used to alkylate the magnesium derivative formed from N-(2-methylpropylidene)cyclohexylamine<sup>12,13</sup> to afford an imine which yielded 3 by hydrolysis with aqueous oxalic acid at 25° for 4 hr.

Wittig condensation of the ylide 1 with the aldehyde 3 in dimethyl sulfoxide<sup>14</sup> afforded the triene 5, Y =

Z = mesityloxy, with the central (5,6) double *cis*.<sup>16</sup> The mesityl and tetrahydropyranyl pro-

groups were removed by sequential treatment with aluminum hydride in ether (25°, 1 hr) and acidic methanol at 25° to give the diol 5, Y = OH, which was converted by phosphorus tri-  
 11 to the dibromide 5, Y = Z = Br.

4,5-*cis* isomer of humulene (6) was formed as the product when a solution of the dibromide 5, Z = Br, in N-methylpyrrolidone was added (automatic syringe drive) to 4 mole equiv of carbonyl in the same solvent at 50° under argon with three other volatile products (0.7, 0.5, 4 parts per part of 6). Irradiation of the crude olefinic product (>350 mμ) and diphenyl disulfide<sup>16</sup> in hexane at 25° for 2.5 hr caused isomerization of humulene (7) which was obtained from the mixture extraction with 50% aqueous silver nitrate.<sup>18</sup> Isolation of pure humulene from the only contaminant readily accomplished by preparative vapor phase chromatography (fluorosilicone column, 150°). The synthetic product behaved exactly as did natural humulene<sup>19</sup> upon vpc analysis with fluorosilicone, diethylene glycol succinate, and Carbowax 20M columns

The *cis* geometry for the 5,6-double bond in 5 is indicated by the observation of the absorption characteristic of *trans* -CH=CH- at 10.3 μ, by the ready photoisomerization using diphenyl disulfide<sup>16</sup> to a product which did exhibit infrared absorption at 10.3 μ, and finally by the observation that the model reaction of pivalaldehyde with *n*-butyl- and *β*-phenylethylidene-triphenylphosphorane in dimethyl sulfoxide afforded olefinic product of >98% *cis* content.<sup>17</sup> The subsequent transformations also allow the *cis* assignment.

## Structures of Two Compounds Containing Strong Metal-to-Metal Bonds

Sir:

It has been established that the  $\text{Re}_2\text{Cl}_8^{2-}$  and  $\text{Re}_2\text{Br}_8^{2-}$  ions have an eclipsed structure<sup>1</sup> with a quadruple bond between the metal atoms.<sup>2</sup> It has been shown that ligand substitution reactions of various kinds proceed readily with these ions.<sup>3</sup> In particular, a compound of empirical formula  $\text{ReCl}_2\text{P}(\text{C}_6\text{H}_5)_3$  was obtained<sup>3a</sup> by treating  $\text{Re}_2\text{Cl}_8^{2-}$  with  $\text{P}(\text{C}_6\text{H}_5)_3$ . Unfortunately this compound, which was shown<sup>3a</sup> not to be of the  $\text{Re}_2\text{Cl}_8\text{L}_2$  type obtained<sup>4</sup> from  $\text{Re}_2\text{Cl}_8$ , was too insoluble to permit positive structural characterization. It was postulated, however, that it is the dinuclear, 1,2-disubstituted derivative,  $(\text{C}_6\text{H}_5)_3\text{PReCl}_2\text{-ReCl}_2\text{P}(\text{C}_6\text{H}_5)_3$ . In order to obtain direct evidence on this, and particularly to see if such a compound retains the short Re-Re bond and the eclipsed configuration which is a consequence<sup>2</sup> of the  $\delta$  component of the quadruple bond, a soluble, crystallizable analog was sought. The  $\text{P}(\text{C}_6\text{H}_5)_3$  analog proved satisfactory; its structure has been determined by single-crystal X-ray methods and is described here.

$\text{Re}_2\text{Cl}_4[\text{P}(\text{C}_6\text{H}_5)_3]_2$  crystallizes in the space group  $\text{P2}_1/\text{n}$  with unit cell dimensions  $a = 7.644 \pm 0.003$ ,  $b = 10.985 \pm 0.005$ ,  $c = 14.206 \pm 0.006$  Å;  $\beta = 96.5 \pm 0.1^\circ$ ;  $Z = 2$ . Intensities were recorded using a counter diffractometer and Cu Kα radiation (Ni filtered) within a sphere limited by  $\theta = 55^\circ$ . The structure was solved by conventional Patterson and Fourier syntheses and has been refined to an  $R$  value<sup>5</sup> of 0.066 neglecting statistically unreliable reflections.

The molecule, shown in Figure 1, lies on a crystallographic inversion center and possesses the expected eclipsed configuration. Important bond lengths and angles are: Re-Re, 2.222 ± 0.003 Å; Re-Cl<sub>1</sub>, 2.35 ± 0.01 Å; Re-Cl<sub>2</sub> and Re-Cl<sub>3</sub>, 2.30 ± 0.01 Å; Re-P, 2.46 ± 0.01 Å; Re-Re-Cl<sub>1</sub>, 116.3 ± 0.2°; Re-Re-Cl<sub>2</sub>, 104.0 ± 0.2°; Re-Re-Cl<sub>3</sub>, 103.0 ± 0.2°; Re-Re-P, 97.4 ± 0.2°. While the significant difference in Re-Cl distances may be explained in terms of the *trans* effect, there is no immediately apparent reason for the observed angular distortions.

This is the first substitution product (not involving oxidation or reduction) of an  $\text{Re}_2\text{X}_8^{2-}$  ion which has

(5) Defined as  $\sum |F_o| - |F_c| / \sum |F_o|$ .

Figure 1. The structure of  $\text{Re}_2\text{Cl}_4[\text{P}(\text{C}_2\text{H}_5)_3]_2$ .

been structurally characterized in a direct and definitive way. It shows that such substitutions can indeed be carried out with preservation of the Re-to-Re quadruple bond with its attendant structural consequences. This result is to be compared with the extensive structural changes (see below) which are sometimes found when  $\text{Re}_2\text{X}_8^{2-}$  species are subjected to redox reactions.

It has recently been reported that a crystalline form of rhenium(IV) chloride exists, from which many chemical reactions produce the  $\text{Re}_2\text{Cl}_8^{2-}$  ion or derivatives thereof.<sup>6</sup> These observations would suggest that the rhenium(IV) chloride contains dinuclear structural units, and one interesting possibility is that such a unit might have a structure similar to that of  $\text{Re}_2\text{Cl}_8^{2-}$  except that the rotational configuration would be staggered and the Re-Re bond longer because of the absence of a  $\delta$  bond, as in the recently reported<sup>7</sup> structure of  $\text{Re}_2\text{Cl}_4(\text{CH}_3\text{SCH}_2\text{CH}_2\text{SCH}_3)_2$ . A single-crystal X-ray study of the structure of the rhenium(IV) chloride has been undertaken. Though dinuclear units are present, they are of an entirely different structure, being of the  $\text{W}_2\text{Cl}_8^{2-}$  type, strung together in infinite chains *via* bridging by one of each set of terminal Cl atoms. Thus, conversion of rhenium(IV) chloride to  $\text{Re}_2\text{Cl}_8^{2-}$  and its derivatives takes place with very extensive rearrangement, *but* the Re-Re unit remains intact.

Rhenium(IV) chloride forms monoclinic crystals belonging to one of the space groups Pc or P2/c. Unit cell dimensions are  $a = 6.366 \pm 0.005$ ,  $b = 6.282 \pm 0.006$ ,  $c = 12.165 \pm 0.006$  Å;  $\beta = 93.17 \pm 0.10^\circ$ . Three-dimensional data were collected using nickel-filtered Cu K $\alpha$  radiation on a GE XRD-5 diffractometer, within the sphere limited by  $2\theta \leq 101^\circ$ . The 425 significant reflections were corrected for Lorentz-polarization effects and absorption. Conventional Patterson and Fourier techniques revealed the structure shown in Figure 2.

Refinement of this structure has been hampered by several severe and seemingly inescapable difficulties, although there is no reason to doubt that, qualitatively, this structure is correct. As reported<sup>6</sup> before, the  $\text{ReCl}_4$  crystals are only metastable and the preparation of them has not been successfully duplicated. The available crystals are relatively large (giving transmission factors for Cu K $\alpha$  radiation ranging from 0.027

Figure 2. A portion of the  $\text{ReCl}_4$  structure projected down the  $b$  axis.

to 0.160) and irregularly shaped so that absorption corrections could not be accurately applied. Attempts to reduce the size or improve the shape of the crystals using either solvents or mechanical grinding failed because of their chemical instability and brittleness. There is also evidence in Laue photographs for disorder. Difference Fourier maps have contained too much noise ( $\sim 2e/\text{\AA}^3$ ) to allow an unambiguous test of the several disorder models which have been postulated. Two independent sets of data on different crystals have been used, each refining (full-matrix, least-squares, P2/c) to  $R \sim 18\%$ . Use of the average of the two sets leads to  $R = 17\%$ . Use of space group Pc makes no significant difference in the course of the refinement. It is possible that by recollecting the data using Mo K $\alpha$  radiation, absorption errors might be minimized enough to permit clarification of the disorder.

The Re-Re distance presently available is  $2.73 \pm 0.03$  Å, which indicates metal-metal bonding. This distance and in fact the entire structure is in marked contrast to that of  $\text{TcCl}_4$ . The latter<sup>8</sup> also contains polymeric chains of  $\text{MX}_4$  octahedra, but joined on edges with Tc-Tc distances of 3.62 Å. Moreover, the Tc atoms are actually displaced away from each other, a good sign<sup>9</sup> that there is no metal-metal bonding. Thus for the four-valent group VII metals, the tendency to form metal-metal bonds becomes dominant only with the third-row metals. However, even a slight lowering of the oxidation state causes Tc as well as Re to form such bonds, as in the  $\text{Tc}_2\text{Cl}_8^{2-}$  ion.<sup>10,11</sup>

Not isolated yield; the mixture was analyzed by gas chromatography on a 6-ft column of 10% Carbowax on Chromosorb P at 110°. Samples were collected on a 2.5-ft column at 110° for spectral comparison analysis or comparison with an authentic sample.

British Patent 840,658 (1960); *Chem. Abstr.*, **55**, 1452 (1961).  $\nu_{\text{max}}^{\text{CHCl}_3}$  1776  $\text{cm}^{-1}$ ; nmr ( $\text{CCl}_4$ ):  $\delta$  3.05 and 4.02 ppm, triplets, 5 cps.

Satisfactory analyses have been obtained for all new compounds reported.

The isolated yield of 3 was 36%; isolated by column chromatography on 80-100 mesh silicic acid followed by distillation.

Similar studies of the photolysis<sup>6</sup> of 8-thiabicyclo[3.2.1]octan-3-one<sup>14,15</sup> (4) in a variety of solvents yielded the products indicated in Table I.

The ultraviolet spectrum of the acyclic  $\gamma$ -keto sulfide 5 shows no charge-transfer band.<sup>16,17</sup> Photolysis of 5 in Freon-113 with a Pyrex, Corex, or Vycor filter yields only polymeric material; photolysis in *t*-butyl alcohol yields predominately polymeric material plus

at least six other products, formed in a total yield of less than 5%.

Since the charge-transfer bands for 1 and 4 extend beyond 280 m $\mu$  and overlap with the  $n, \pi^*$  band, our results do not enable us to conclude whether charge transfer or  $n, \pi^*$  excitation is responsible for the observed products.<sup>18</sup>

(3)  $\lambda_{\text{max}}^{\text{isothiochroman}}$  244.5 m $\mu$  ( $\epsilon$  10,400), 289 (1540), 348 (149).

(4) Satisfactory analyses have been obtained on all new compounds reported.

(5)  $\nu_{\text{max}}^{\text{CCl}_4}$  1723, 1468, 1443, 1385, 1253, 1236, 951, 500, 440  $\text{cm}^{-1}$ ;  $\lambda_{\text{max}}^{\text{isothiochroman}}$  254 m $\mu$  ( $\epsilon$  6900), 357 (150); nmr:  $\delta$  3.15 (2 H, singlet,  $-\text{SCH}_2-\text{CO}-$ ), 3.55 (2 H, singlet,  $\text{ArCH}_2\text{CO}-$ ), 6.9-7.8 (4 H, multiplet, ArH).

boxylation. Photolysis of 1 under similar conditions in a Rayonet reactor, 3500-A source,<sup>6</sup> resulted in very slow decomposition to polymeric material, indicating excitation of only the long-wavelength band is not sufficient for the reaction.

We believe that the initial photoproduct is the triene 2 which undergoes a further photochemically induced rearrangement to 3. In an effort to obtain evidence for the intermediacy of 2 in the reaction, 5<sup>4,7</sup> was irradiated under similar conditions in the hope of isolating 6, which should not undergo further photochemical rearrangement if excitation of the triene system is responsible for further photochemical rearrangement of 2. Photolysis<sup>1</sup> of 5 in cyclohexane produced 6<sup>8</sup> in 30% yield. This observation and the appearance of an absorption band at 1770 cm<sup>-1</sup> in the infrared spectrum of a solution of 1 in cyclohexane which had been photolyzed for a short period of time suggest that 2 is a reasonable intermediate in the formation of 3.

8-Methyl-, 7-methoxy-, 3-methyl-, and 3,3-dimethylisothiochroman-4-one also undergo this photochemical rearrangement in yields varying from 20 to 40%.<sup>9</sup>

postulated<sup>7</sup> that the hydrolysis of phosphate esters may, and in some cases must, proceed with pseudo-rotation<sup>8,9</sup> of trigonal-bipyramidal intermediates. In contrast to methyl ethylene phosphate, the methyl ester of the five-membered cyclic phosphinic acid hydrolyzes at a rate comparable to that of the ester of diethylphosphinic acid.<sup>6,10</sup> This fact can be explained by postulating that, in analogy with the known chemistry of the alkylfluorophosphoranes,<sup>11</sup> oxygen atoms preferentially occupy the apical, and alkyl groups the equatorial positions in the trigonal-bipyramidal intermediates formed during hydrolysis. Under these assumptions, the hydrolysis of the ester of the cyclic phosphinic acid is slow, despite the presumed strain in the ring, because, in order to form a trigonal-bipyramidal intermediate, an alkyl group must be forced into an unfavorable axial position, or else the ring angle must be expanded to 120°. Both kinetic<sup>4,7</sup> and X-ray crystallographic<sup>12</sup> evidence as well as theory<sup>8</sup> argue against this latter choice. The chemistry of phosphonates<sup>7</sup> can also be rationalized on the assumption of preferential placement of alkyl groups in equatorial positions in trigonal-bipyramidal intermediates in hydrolysis. Ramirez and his co-workers<sup>13</sup> have prepared many cyclic phosphoranes, including<sup>14</sup> I, where an alkyl group is part of a five-membered ring system. According to our postulates,<sup>7</sup> this compound should exist preferentially in a structure where the alkyl group is equatorial, and where therefore the methoxyl groups occupy different positions. However, the nmr spectrum of I, determined at room temperature,<sup>14</sup> shows only one kind of methoxyl group.

We now report that, at low temperatures, the nmr spectrum of I corresponds to that expected for the structure as shown. At room temperature, the three

## Inhibited Pseudo-Rotation in a Cyclic Monoalkylphosphorane<sup>1</sup>

Sir:

Methyl ethylene phosphate undergoes hydrolysis, both to open the ring and to lose the methoxyl group, at a rate about a million times as great as that for trimethyl phosphate.<sup>2</sup> The driving force for the rapid reactions is presumably ring strain.<sup>3</sup> However, to explain the unexpected rapid hydrolysis of the ester group external to the ring in methyl ethylene phosphate and various other cyclic compounds<sup>2,4-6</sup> we recently

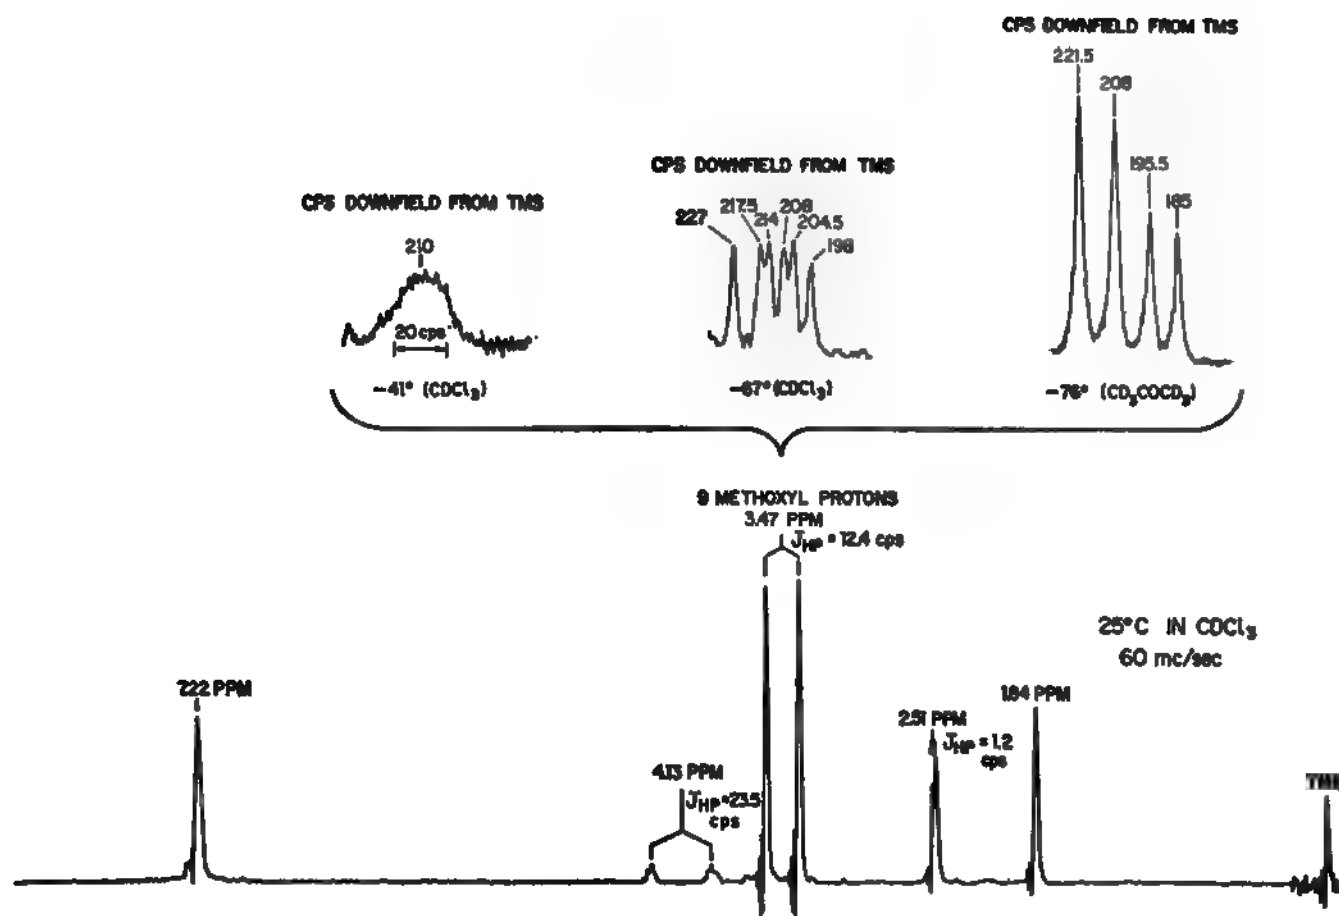

Figure 1. The proton nmr spectrum, at 60 Mc, for I at 25, -41, and -67° in deuteriochloroform, and -76° in deuterioacetone.

methoxyl groups appear as a doublet; the signal is split by  $^{31}\text{P}$  with  $J = 12.5$  cps. In either deuteriochloroform or in deuterioacetone, the doublet observed at room temperature collapses, at about  $-40^\circ$ , to a broad band, and at  $-65^\circ$  this band is again resolved (Figure 1). In deuterioacetone, the nmr spectrum of the methoxyl groups shows two separate doublets, with  $J = 13.5$  and 10.5 ppm and with integrated intensities of 1:2, corresponding to one apical and two equatorial methoxyl groups, whereas in deuteriochloroform the spectrum shows three partially separated doublets, two with  $J = 13$  and one with  $J = 10$  cps. These again correspond to one apical and two equatorial methoxyl groups. Since the two equatorial methoxyl groups in I differ in their relationship to the phenyl ring, it is the acetone spectrum, rather than that in chloroform, that is somewhat unexpected. In contrast to I, the pentaoxyphosphorane III shows only one kind of methoxyl groups (a sharp doublet,  $J = 13$  cps) all the way down to  $-100^\circ$ . For III, pseudo-rotation necessarily generates unstrained structures with apical oxygen atoms; the equivalence of positions in this compound resembles that<sup>8,11</sup> of  $\text{PF}_5$ .

The low-temperature nmr spectra in Figure 1 show that I is stable with equatorial alkyl group. The constancy of the average chemical shift for the methoxyl groups and of the coupling constants shows that, at high temperature, exchange occurs among equivalent structures. Pseudo-rotation about an equatorial methoxyl group as pivot will convert I to II; two methoxyl groups of II are equivalent, and the pseudo-rotation from II to I can utilize a different

methoxyl group as pivot than that for its formation. Further pseudo-rotations can complete the exchange process. Although II is energetically unfavorable with respect to I, its formation in minute amount and reversion to I is apparently sufficiently rapid at room temperature to catalyze the exchange of the methoxyl groups; II functions as does the boat form of cyclohexane in the interconversion of equivalent chair forms. An alternative mechanism for exchange of the methoxyl groups allows the opening of the five-membered ring<sup>16</sup> to form IV, followed by mixing of the methoxyl groups by rotation and reclosure of the ring. Even if such a mechanism is operative, it does not in any way affect the conclusion that, at low temperatures, the structure of I is frozen as drawn, that pseudo-rotation is inhibited, and that in derivatives of phosphorane alkyl groups preferentially occupy equatorial and oxygen atoms apical positions. But the explanation involving ion pairs is relatively unlikely. First, the enolate ion in IV must be more stable than the corresponding enolate in an ion pair derived from III; if the formation of ion pairs were the only mechanism for exchange, I should undergo the reaction more readily, rather than less readily, than III. But further, the temperature at which the doublet for I coalesces is about  $-41^\circ$  in deuteriochloroform and  $-37^\circ$  in deuterioacetone, but about  $-60^\circ$  in deuteriotoluene. If the exchange among the methoxyl groups occurred by way of an ion pair, this exchange should prove more facile, rather than less facile, in the more

### Contact and Solvent-Separated Ion Pairs of Carbanions. III. Reactivities in Proton-Abstraction Reactions

Sir:

It was recently shown<sup>1</sup> that changes in the absorption spectra of solutions of carbanions and radical ions upon varying the solvent composition and temperature could be interpreted in terms of two kinds of ion pairs, *i.e.*, contact and solvent-separated ion pairs. We have now studied the reactivity behavior of these species in proton-abstraction reactions and have made a number of interesting observations.

Alkali salts of the fluorenyl carbanion were allowed to react with 1,2- or 3,4-benzofluorene in dioxane, tetrahydrofuran, or 1,2-dimethoxyethane as solvent. The progress of the reaction was followed spectrophotometrically, and the rate constants were calculated from the initial slopes of the recorder tracings. In a number of instances a flow system was used, but even then some of the reactions were too rapid to obtain accurately the initial slopes. In these cases calculation of the rate constants was based on the half-life of the reaction. Although this will somewhat affect the accuracy of the data, the differences between the observed second-order rate constants for the various systems are large enough to justify a comparison. The results are reported in Table I.

The data for fluorenyllithium show a strong dependence of the rate constants on the carbanion concentration in all three solvents. The same is true of fluorenylsodium in dioxane. This suggests the presence of unreactive aggregates,  $[F^-, M^+]_n$ , in these solutions, and the kinetic measurements lead to an average aggregation number of 5 or even higher. This strong association, even in solvents like THF and DME, is surprising since no such association was observed for the less charge delocalized polystyryl salts in either THF or dioxane.<sup>2</sup> It is likely that the association of the fluorenyl salts is favored by the planar structure of the carbanion. This may lead to a sandwich-type aggregate in which many ion pairs are stacked up

An additional attractive force, particularly important for the lithium salts, may result from a tendency of the counterion to complex with the highly polarizable  $\pi$  cloud of the fluorenyl ring.

Aggregation persists, at least for the lithium salts, even in THF and DME, where the ion pairs are solvent separated. This suggests that in the solvent-separated ion pair of fluorenyllithium the counterion is not fully surrounded by solvent molecules, since aggregation would then be sterically unfavorable and expected to be less than for the poorly solvated fluorenylcesium. Apparently, the lithium ion assumes a new average position in the solvent-separated ion pair; away from the carbanion but yet still close to the  $\pi$ -electron cloud of the ring system (see Figure 1). Such a position, made possible because of increased association with solvent molecules, would also lead to the observed red shift in the spectrum as compared to the contact ion pair and would at the same time energetically be favorable because of  $\pi$  complexing. Rate measurements with dioxane solutions of fluorenyllithium containing varying quantities of dimethyl sulfoxide again point to strong association of both contact and solvent-separated ion pairs in these systems. This type of association may well be responsible for the large discrepancies observed in the values for proton-transfer rate constants in solutions of fluorenyllithium in dimethyl sulfoxide,<sup>3</sup> in which different techniques and different carbanion concentrations were used.

Another interesting observation concerns the role of the counterion in proton-abstraction reactions. At low concentrations (*i.e.*, under conditions where aggregation vanishes), fluorenylsodium is as reactive or even more so in dioxane than in THF, while a strong increase in the rate constant is observed in DME. In the first two solvents the sodium salt is a contact ion pair, while in DME it is essentially solvent separated. Hence, less energy is needed in the latter case to transfer

(3) J. I. Brauman, D. F. McMillen, and Y. Kanazawa, *J. Am. Chem. Soc.*, **89**, 1728 (1967); C. D. Ritchie and R. E. Uschold, *ibid.*, **89**, 1730 (1967).

1. A represents an aggregate of contact ion pairs ( $F^-$ ,  $M^+$ )<sub>n</sub> that of solvent-separated ion pairs. The arrow denotes g molecules inducing a shift of the counterion to a new position away from the center of negative charge.

unterior to the new carbanion. For the tetrammonium salt, the reactivity is found to be the in THF as in DME. No solvent-separated ion are observed for this salt in either solvent! How-the Coulomb interaction between carbanion and erion is not the only rate-determining factor, since nylcesium would then be expected to have a higher ivity than fluorenylsodium in both dioxane and

The reverse is true, which suggests that the rion activates the benzofluorene molecule and ates the proton-abstraction process (see Figure uch an activation has been suggested in other ons involving organometallic reagents.<sup>4</sup> The e-ill rapidly decrease with increasing size of the erion and may be essentially absent for cesium trabutylammonium (the association of the lithium revented us from obtaining the rate constant for hium ion pair).

s significant that addition of the strongly dis- le  $NaB(C_6H_5)_4$  does not decrease the rate of the on but seems to even increase the rate slightly. rently, the free carbanion is not more, and pre- ly even less, reactive than the contact ion pair. ould also explain the concentration independence : rate constants for the sodium and cesium salts [F in spite of the increased free ion formation at oncentration.<sup>5</sup> These results are in agreement he catalyzing role assigned to the counterion.

: solvent-separated ion pair, where Coulomb inter- has greatly weakened, would be highly reactive g as the counterion can effectively activate the fluorene molecules. This appears to be the case -dimethoxyethane. However, when the solvating prevents a close approach between the benzo- ne molecule and the counterion, the solvent- ed ion pair reactivity is expected to be less than f the contact ion pair and may approach that of ee ion. Such appears to be the case in the system nylsodium-tetrahydrofuran to which small quan- of tetraethylene glycol dimethyl ether were added. e presence of this powerful solvating agent<sup>6</sup> the um shows complete solvent-separated ion pair tion, yet the rate of proton abstraction is slower in the absence of this reagent. Its high solvating arises from the fact that probably all five oxygens ilized in the solvation of the sodium ion and there- effectively shield this ion from interaction with the fluorene molecule.

Figure 2. Activating role of the positive ion in proton-abstraction reactions. A and B represent the fluorenyl carbanion and the benzofluorene molecule, respectively.

The behavior of these carbanion salts in proton-abstraction reactions is the more interesting when the results are compared with those of addition reactions involving carbanions. In the anionic polymerization of styrene in THF<sup>2</sup> the free polystyryl ion was found to be about 800 times more reactive than the sodium contact ion pair, while the solvent-separated ion pair reactivity approaches that of the free ion.<sup>7</sup> In dioxane the ion pair reactivity increases substantially in the order  $Li < Na < Cs$ .<sup>8</sup> Both results indicate that in these reactions the Coulombic interaction between the carbanion and the counterion is of far greater importance than any possible interaction between the counterion and the reacting monomer, at least in ethereal solvents. Other types of carbanions and substrates will be investigated in order to establish whether the behavior of fluorene and its derivatives in proton abstraction reactions is unique in this respect.

### Indirect $^{15}N$ - $^1H$ Spin-Spin Couplings in Quinoline- $^{15}N$ , Its Ethiodide, and Its N-Oxide. Relative Signs and Solvent Dependence

Sir:

Previous observations,<sup>1,2</sup> of some interest, on the spin couplings between a nitrogen-15 nucleus in an aromatic ring and ring protons have prompted us to report here the correlation of indirect  $^{15}N$ - $^1H$  couplings with the electronic nature of the  $^{15}N$  atom as studied by using quinoline- $^{15}N$  (I), its ethiodide (II), and its N-oxide (III).<sup>3</sup> Coupling constants,  $J$ , in these compounds were obtained by comparing the pmr spectra of the  $^{15}N$  compounds with those of the corresponding  $^{14}N$  compounds in a variety of solvents (see Table I).<sup>4</sup> A pair of the pmr spectra of quinoline- $^{14}N$  and - $^{15}N$  in acetone- $d_6$  is shown in Figure 1 as an example.

(3) For the synthesis of III (97 atom %), see ref 1. I and II were successively prepared from III in the usual way.

(4) Pmr spectra were taken with a Varian HA-100 spectrometer operating at 100 MHz in the frequency-swept and TMS-locked mode,

Table I. Summary of  $^{15}\text{N}$ - $^1\text{H}$  Spin-Coupling Constants (in Hz)

Compound		Solvent		
		Aprotic solvents <sup>a</sup>	$\text{CH}_3\text{COOD}$	$\text{D}_2\text{SO}_4$ and $\text{CF}_3\text{COOD}$
I 	$J_{\text{N},\text{H}(2)}$	-11.1	-4.5	-2.0
	$J_{\text{N},\text{H}(4)}$	-1.4	-3.1	-4.5
II 	$J_{\text{N},\text{H}(2)}$	-1.6 <sup>b</sup>	-1.6	... <sup>c</sup>
	$J_{\text{N},\text{H}(4)}$	-4.3 <sup>b</sup>	-4.3	-4.4
III 	$J_{\text{N},\text{H}(2)}$	~0	~+1	+1.2
	$J_{\text{N},\text{H}(4)}$	-5.0	-5.5	-6.0

<sup>a</sup> Aprotic solvents used were cyclohexane,  $\text{CCl}_4$ ,  $\text{C}_6\text{D}_6$ ,  $\text{C}_5\text{D}_5\text{N}$ ,  $\text{CH}_3\text{CN}$ , dioxane, acetone- $d_6$ , and/or DMSO- $d_6$ . Other solvents used as protic ones were  $\text{CDCl}_3$ ,  $\text{D}_2\text{O}$ , and/or  $\text{D}_2\text{O}$ -dioxane (1:1)- $\text{DCl}$  system. <sup>b</sup> Values obtained in  $\text{D}_2\text{O}$ . <sup>c</sup> Obscured by overlapping of other signals.

Since coupling constants between ring protons in quinoline were already found to have a positive sign,<sup>6</sup> the relative sign of  $J_{\text{N},\text{H}(2)}$  and  $J_{\text{N},\text{H}(4)}$  was determined in an acetone- $d_6$  solution by using partial spin-decoupling technique. The  $^{15}\text{N}$ , H(2), H(3), and H(4) nuclei can be treated as an isolated first-order, four-

Figure 1. PMR spectra of quinoline- $^{15}\text{N}$  and - $^{14}\text{N}$  in acetone- $d_6$  at 100 MHz and the spin-state diagram.

spin system by neglecting  $J_{\text{H}(4),\text{H}(3)}$ . On double irradiation on the lines q, r, s, and t, the lines a and c and the lines e and g collapse to two single peaks, whereas irradiation on the lines u, v, w, and x causes collapsing of the lines b and d, and the lines f and h (see Figure 1). These results can be well explained by the spin states shown in Figure 1 (bottom); this indi-

cates that  $J_{\text{N},\text{H}(2)}$  and  $J_{\text{N},\text{H}(4)}$  are of the same sign although the sign of these  $J$ 's relative to  $J_{\text{N},\text{H}(3)}$  could not be determined because of the small magnitude of the latter,  $J_{\text{H}(2),\text{H}(3)}$ , and  $J_{\text{H}(3),\text{H}(4)}$ .<sup>6</sup> Since the magnetogyric ratio of the  $^{15}\text{N}$  nucleus has a negative sign, the absolute sign of these  $J$  values can reasonably be assumed to be negative by analogy with the fact that the  $J_{\text{N},\text{C}-\text{C}-\text{H}}$  values in trimethylvinylammonium bromide<sup>7</sup> and alkyl isonitriles<sup>8</sup> have a positive sign.<sup>9</sup>

(9) Refer to A. J. R. Bourn, D. G. Gillies, and E. W. Randall, "Nuclear Magnetic Resonance in Chemistry," B. Pesce, Ed., Academic Press Inc., New York, N. Y., 1965, p 277.

it play a significant role in these facts, although the contribution due to changes in  $\pi$ -electron structures can be completely excluded. Further, this conclusion is supported by the similar behavior reported on  $J_{\text{H-P-C-H}}$   $J_{\text{H-P-C-H}}$ ,<sup>10</sup> when the reduced coupling constants compared. The former  $J$  value decreases algebraically whereas the latter, which is always positive, increases as the  $^{31}\text{P}$  atom becomes more cationic ( $\text{P} \rightarrow \text{P}^+$ ).

It should also be noted that whenever the signals concerned were separately observed, the presence of weak couplings (about 1 Hz or less), although not experimentally measured, were clearly discernible for  $|J_{\text{N,H(4)}}|$   $|J_{\text{N,H(4)}}|$ , which are considerably smaller than  $|J_{\text{H(4)}}|$  in all the cases examined (see Figure 1, for example).<sup>11</sup>

### Synthesis of N<sup>4</sup>-Acetyl-3,4,5,6-tetrahydrocytidine Copolymers of Cytidylic Acid and N<sup>4</sup>-Acetyl-3,4,5,6-tetrahydrocytidylic Acid

Recent studies of the optical rotatory dispersion spectra of poly C<sup>1,2</sup> and poly U<sup>3</sup> at neutral pH, and of the reduction of poly C<sup>3</sup> and poly A<sup>4</sup> with formaldehyde, led to the conclusion that intra- or interstrand hydrogen bonding plays a negligible role in the stabilization of the secondary structure of these polymers. It has been suggested for these polymers that a single-stranded helical structure is stabilized by interactions of the reduced bases. Polynucleotides containing residues of a saturated and therefore nonplanar heterocyclic nucleoside are suitable model compounds for studying this thesis. Saturated nucleotides are unlikely to participate in base stacking due to their stereochemistry and their shortened  $\pi$ -electron system.<sup>5</sup> Copolymers containing saturated nucleotide residues are also suitable model compounds for yeast transfer RNA, where 5,6-dihydrouridine has been detected as a minor constituent.<sup>6</sup> We wish to report the synthesis of N<sup>4</sup>-acetyl-3,4,5,6-tetrahydrocytidine and copolymers of cytidylic acid containing varying amounts of N<sup>4</sup>-acetyl-3,4,5,6-tetrahydrocytidylic acid as nonplanar constituents.

While cytidine is completely resistant toward sodium borohydride in the dark,<sup>7</sup> N<sup>4</sup>-acetylcytidine is reduced

Figure 1. The reduction and deacetylation of N<sup>4</sup>-acetylcytidine in the presence of sodium borohydride in the dark. Disappearance of N<sup>4</sup>-acetylcytidine calculated from the absorption at 310 m $\mu$  in 1 N HCl ( $\bullet$ , 14 M excess NaBH<sub>4</sub>;  $\Delta$ , 140 M excess NaBH<sub>4</sub>;  $\epsilon_{310}$  N<sup>4</sup>-acetylcytidine  $18 \times 10^3$ ); formation of N<sup>4</sup>-acetyl-3,4,5,6-tetrahydrocytidine, orcinol assay ( $\circ$ , 14 M excess NaBH<sub>4</sub>;  $\Delta$ , 140 M excess NaBH<sub>4</sub>). Inset: formation of cytidine calculated from the absorption at 310 m $\mu$  and 270 m $\mu$  in 1 N HCl ( $\bullet$ , 14 M excess NaBH<sub>4</sub>;  $\Delta$ , 140 M excess NaBH<sub>4</sub>;  $\epsilon_{310}$  N<sup>4</sup>-acetylcytidine  $18 \times 10^3$ ,  $\epsilon_{270}$  N<sup>4</sup>-acetylcytidine  $23 \times 10^3$ ,  $\epsilon_{310}$  cytidine 0,  $\epsilon_{270}$  cytidine  $10 \times 10^4$ ); deacetylation of N<sup>4</sup>-acetylcytidine in the absence of NaBH<sub>4</sub> at pH 10 ( $\circ$ , from the disappearance of the absorption at 310 m $\mu$  measured in 1 N HCl;  $\epsilon_{310}$  N<sup>4</sup>-acetylcytidine  $18 \times 10^3$ ).

to N<sup>4</sup>-acetyl-3,4,5,6-tetrahydrocytidine and partially deacetylated to cytidine in the presence of sodium borohydride at pH 10. The rate of the reduction and deacetylation<sup>8</sup> are both dependent on the concentration of sodium borohydride. N<sup>4</sup>-Acetylcytidine is also deacetylated at a slower rate at pH 10 in the absence of the reducing agent. The extent of the reduction can be determined with the orcinol assay for ribose due to the labilization of the N-glycoside bond upon saturation of the 5,6 double bond in N<sup>4</sup>-acetylcytidine. The disappearance of N<sup>4</sup>-acetylcytidine and the formation of cytidine can be followed spectrophotometrically and the composition of the reaction mixture calculated at each point of the reaction from the absorbance at 310 and 270 m $\mu$  in 1 N HCl<sup>9</sup> (see Figure 1). The final yield of N<sup>4</sup>-acetyl-3,4,5,6-tetrahydrocytidine was 54% if a 14 M excess of sodium borohydride was used and 45% at a 140 M excess of the reducing agent. In both cases

(7) P. Cerutti and N. Miller, *J. Mol. Biol.*, in press.

(8) The deacetylation reaction is reminiscent of the reductive deacetylation of N-acylindoles and carbazoles with NaBH<sub>4</sub> (K. Banholzer, T. W. Campbell, and H. Schmid, *Helv. Chim. Acta*, **35**, 1577 (1952)).

(9) N<sup>4</sup>-Acetyl-3,4,5,6-tetrahydrocytidine has no appreciable absorption at wavelengths longer than 250 m $\mu$ .

44% cytidine was formed. If the reaction was carried out under ultraviolet irradiation (2537 Å) the yield for the reduction product was 76% and for cytidine 21% (14 *M* excess of NaBH<sub>4</sub>).<sup>10</sup>

The two components of the reduction mixture, cytidine and N<sup>4</sup>-acetyl-3,4,5,6-tetrahydrocytidine, were separated by column chromatography on Dowex 50W-X8 (H<sup>+</sup>). The structure of the reduction product was derived from the nmr spectrum (in D<sub>2</sub>O). A triplet at 5.30 ppm (*J* = 4.5 cps, 1 H) was attributed to the proton at C<sub>4</sub> and a multiplet centered at 3.39 ppm (2 H) to the methylene protons at C<sub>5</sub>. A multiplet at higher field was superimposed by a singlet originating from the methyl group of the acetyl substituent (singlet at 1.99 ppm) and was attributed to the methylene protons at C<sub>5</sub>. The signal at 5.30 ppm disappeared and the multiplet at 3.39 ppm was simplified and lowered in intensity if the reduction was carried out with sodium borodeuteride. The product of the reduction with sodium borodeuteride is therefore N<sup>4</sup>-acetyl-3,4,5,6-tetrahydrocytidine-*d*<sub>4</sub>,*d*<sub>5</sub> (II). The isotope distribution in II suggests the following reaction steps: (1) 1,4 addition of a hydride (deuteride) ion (at C<sub>4</sub>) and a proton (at N<sup>3</sup> or N<sup>4</sup>) to an α,β-unsaturated imine, and (2) further reduction of the intermediate N<sup>4</sup>-acetyldihydrocytidine (I) by the attack of a second hydride (deuteride) ion at C<sub>4</sub>.

This novel reaction was used for the synthesis of copolymers of cytidylic acid and N<sup>4</sup>-acetyl-3,4,5,6-tetrahydrocytidylic acid by the reduction of copolymers of cytidylic acid and N<sup>4</sup>-acetylcytidylic acid.<sup>11</sup> The polymers were exposed to a large excess of sodium borohydride in 0.05 *M* sodium carbonate buffer at pH 9.8 for 40 min at room temperature. The polymers were purified by repeated precipitation with cold ethanol and by passage through Sephadex G-25. The composition of the polymers was determined spectrophotometrically and with the orcinol assay after total digestion with pancreatic ribonuclease. In contrast to the behavior of the monomer no significant deacetylation was observed. Polymers containing 8, 16, and 29%

(10) No spectral changes were detected if N<sup>4</sup>-acetylcytidine was irradiated under the analogous conditions for 70 min in the absence of NaBH<sub>4</sub>.

N<sup>4</sup>-acetyl-3,4,5,6-tetrahydrocytidylic acid were prepared by this method, and their physical properties are being investigated. The characterization of the polymers is given in Table I. The presence of N<sup>4</sup>-acetyl-3,4,5,6-tetrahydrocytidine in the reduced polymer demonstrated in experiments using sodium borotri as a reducing agent. The components of the nuclease digest were separated on Dowex 50W

Table I. Characterization of the Polymers

Compn before reduction, %		Compn after reduction, %	
Cytidine 3'-phosphate <sup>a</sup>	N <sup>4</sup> -Acetylcytidine 3'-phosphate <sup>a</sup>	Cytidine 3'-phosphate <sup>b</sup>	N <sup>4</sup> -Acetyl-3,4,5,6-tetrahydrocytidine 3'-phosphate <sup>b</sup>
68	26	73	29
81	18	84	16
90	7	90	8

<sup>a</sup> The amounts of cytidine 3'-phosphate and N<sup>4</sup>-acetylcytidine 3'-phosphate were calculated from the absorbance of the nucleic mixture obtained from the digestion of the polymers with creatic ribonuclease in 0.05 *M* NH<sub>4</sub>HCO<sub>3</sub>, pH 7.5, at 270 mμ (ε<sub>270</sub> cytidine 3'-phosphate 9 × 10<sup>4</sup>; ε<sub>270</sub> N<sup>4</sup>-acetylcytidine 3'-phosphate 4.4 × 10<sup>4</sup>; ε<sub>270</sub> N<sup>4</sup>-acetylcytidine 8.6 × 10<sup>4</sup>). To accomplish complete deacetylation the samples were then kept for 6 hr at 65–70° the cytidine 3'-phosphate content was determined from the absorbance at 280 mμ (ε 1.3 × 10<sup>4</sup>, pH 1). This value was taken 100% for the calculation of the base composition of the polymer.

<sup>b</sup> The amount of cytidine 3'-phosphate was determined from the absorbance of the nucleotide mixture obtained from the digestion of the reduced polymers with pancreatic ribonuclease at 280 mμ (ε 1.3 × 10<sup>4</sup>, pH 1). The content of N<sup>4</sup>-acetyl-3,4,5,6-tetrahydrocytidine 3'-phosphate was measured with the orcinol assay. The polymer phosphate was determined according to B. N. Ames, D. T. Dubin, *J. Biol. Chem.*, 235, 769 (1960), and taken as a basis for the calculation of the base composition of the polymer.

(H<sup>+</sup>). The fractions containing radioactive material were treated with alkaline phosphomonoesterase; their content was compared to authentic N<sup>4</sup>-acetyl-3,4,5,6-tetrahydrocytidine by thin layer chromatography (silica gel G, 85% 2-propanol). Identical R<sub>f</sub> values were found for the radioactive compound derived from the polymer and for N<sup>4</sup>-acetyl-3,4,5,6-tetrahydrocytidine obtained from the reduction of the monomer. Radioactivity was found in the eluates containing cytidylic acid.

Attempts are now being made to synthesize copolymers of cytidylic acid and 3,4,5,6-tetrahydrocytidylic acid by the reduction of N<sup>4</sup>-formylated and N<sup>4</sup>-fluoroacetylated polycytidylic acid followed by deacetylation.

**Acknowledgment.** This research was supported by Grants GB 4894 from the National Science Foundation, GM 14090-01 from the National Institute of Health, and a grant from Hoffmann-La Roche, Nutley, N. J.

## Rate Constants and the Mechanism for the Transfer of Triplet Excitation Energy

Sir:

The intramolecular transfer of triplet excitation energy from one chromophore to another has been measured

s I and II shown in Figure 1. The triplet donor is ester of benzophenone-4-carboxylic acid, and triplet donor in II is the carbazole chromophore. The acceptor in both cases is the naphthalene chromophore. The absorption spectrum of each molecule is the sum of the absorption spectra of their chromophores. The lowest singlet state of both donors is lower in energy than the lowest singlet state of naphthalene. This makes it possible to excite donors with long wavelength radiation which is absorbed by the naphthalene chromophore. All measurements were made at 77°K in a rigid matrix.<sup>1</sup>

The phosphorescence spectrum of a very dilute solution ( $10^{-5} M$ ) of II shows emission from both the carbazole chromophore ( $\sim 63\%$ ) and the naphthalene chromophore ( $\sim 37\%$ ). The intensity of phosphorescence from II is about 67% as strong as the intensity of phosphorescence of an equimolar mixture of naphthalene and III at the same concentration. The lifetime of carbazole emission from II is 5.7 sec,<sup>2</sup> while the lifetime of the carbazole emission from III is 7.2 sec. The difference of the first-order rate constants (calculated from lifetimes) indicates that 21% of the triplet energy is transferred and that the rate constant for the transfer process is about  $0.04 \text{ sec}^{-1}$ . The agreement between these three completely different measurements for the amount transferred is excellent. The first method is the least accurate as it involves a knowledge of the phosphorescence quantum yields for the two chromophores, and it involves intensity measurements at different wavelengths.

No corrections were made for the change in sensitivity of the apparatus as a function of wave-

length. The phosphorescence spectrum of a very dilute solution ( $10^{-4} M$ ) of I shows emission from both the naphthalene and the benzophenone chromophore. The lifetime of the phosphorescence from the benzophenone chromophore is almost 1000 times shorter than the phosphorescent lifetime of the naphthalene chromophore. A measurement of the ratio of the intensities of the singlet and slow components of I indicated that 74% of the triplet excitation energy was transferred to the naphthalene chromophore. The phosphorescence from I is about 65% as intense as the phosphorescence from an equimolar mixture of IV and naphthalene.

This indicates that about 35% of the triplet energy is transferred. The lifetime of the phosphorescence emission from I is  $4.9 \times 10^{-3} \text{ sec}$  and the lifetime of the naphthalene emission is  $5.6 \times 10^{-3} \text{ sec}$ . The difference of the first-order rate constants indicates that 12% of the triplet energy is transferred and that the rate constant for the transfer process is  $25 \text{ sec}^{-1}$ . The agreement between these two sets of measurements is not quite as good for

butyl alcohol and 70% isopentane.

The decay was very slightly nonexponential at very short times. This is due to a distribution in the distances between the chromophores. The lifetime quoted was from the exponential part of the decay.

The quantum yields of naphthalene and carbazole were assumed to be the same for this calculation. The intersystem quantum yields for these compounds were found to be the same by A. A. Lamola and J. R. Lakshminarayanaiah, "Photochemistry," John Wiley and Sons, Inc., New York, 1952, p 209.

Corrections were made for the sensitivity of the apparatus as a function of wavelength. The phosphorescent quantum yield of the benzophenone chromophore was assumed to be ten times the phosphorescent quantum yield of the naphthalene chromophore.

Figure 1. Molecules studied: (I) 3-( $\alpha$ -naphthyl)-5 $\alpha$ -androstan-17 $\beta$ -ol 17-*p*-benzoylbenzoate, (II) 3-( $\alpha$ -naphthyl)-5 $\alpha$ -androstan-17 $\beta$ -ol 17-(9-carbazole)acetate, (III) ethyl (9-carbazole)acetate, (IV) ethyl *p*-benzoylbenzoate.

I as it is for II, but all measurements agree within a factor of 3. The lifetime measurement is probably the most accurate because it does not involve a comparison of two intensities or an assumption of quantum yields.

The transfer of singlet excitation energy from the naphthalene chromophore to the two donor chromophores was measured by comparing the intensity of the naphthalene emission from an equimolar mixture of naphthalene and either III or IV to the intensity of the naphthalene emission from I or II; 2985-Å radiation was used for excitation. These measurements indicated that in I, 70% of the singlet excitation energy is transferred and in II, 95% of the singlet excitation energy is transferred. A dipole-dipole coupling mechanism was assumed to be responsible for the transfer of singlet excitation energy and Förster's equation<sup>5</sup> was used to calculate the distance between the chromophores. The distances were found to be 14 Å for I and 15 Å for II. These numbers agree very well with

(5) Th. Förster, *Discussions Faraday Soc.*, 27, 7 (1959). The exponent on  $r$  should be 5 instead of 6; see S. A. Latt, H. T. Cheung, and E. R. Blout, *J. Am. Chem. Soc.*, 87, 995 (1965).

measurements of the distances made on molecular models.

In summary, the rate constant for triplet excitation transfer in I ( $25 \text{ sec}^{-1}$ ) is about 1000 times greater than in II ( $0.040 \text{ sec}^{-1}$ ). The transfer distance is about the same in both cases. The mechanism suggested by these results involves spin-orbital coupling to the singlet system in the donor chromophore combined with dipole-dipole coupling between the singlet systems of the two chromophores and spin-orbital coupling back to the triplet system in the acceptor chromophore. The difference of 1000 in the rate constant for transfer is the result of the large difference in spin-orbital coupling between III and IV which is exemplified by the large difference (again a factor of 1000) in their phosphorescent lifetimes. A mechanism involving exchange integrals would not be expected to lead to such a large difference in the transfer properties of the two compounds. Also, it is unlikely that an exchange integral mechanism could be operative at such large distances.

A more complete description of these measurements is currently in preparation.

## Preparation and Properties of Monocesium Chloroxenate ( $\text{CsClXeO}_3$ )<sup>1</sup>

Sir:

We wish to report preparation of a stable, crystalline cesium xenon(VI) compound containing chloride similar to the cesium fluoroxenate ( $\text{CsFXeO}_3$ ) reported by Selig<sup>2</sup> and Spittler, *et al.*<sup>3</sup> The crystalline cesium chloroxenate can be prepared either from aqueous solutions at pH 8 to 9 or from acetonitrile. A crystalline precipitate is obtained by mixing ice-cold solutions of approximately 2.0 ml of 1.5 *M* cesium chloride with 0.4 ml of 1.5 *M* xenon trioxide or by adding xenon trioxide to cesium chloride dropwise until permanent turbidity appears. Then the solution is left in the icebox for approximately 3 hr. The supernatant solution is sucked off, and the crystals first are washed with several portions of ice-cold water and finally with acetonitrile. The contents are dried in a vacuum desiccator. Preparation of cesium chloroxenate must be carried out in slightly alkaline medium otherwise chloride is oxidized to chlorine oxides and forms highly explosive solutions. Crystalline cesium chloroxenate also can be prepared by mixing approximately equal volumes of 0.1 *M* cesium chloride and 0.1 *M* xenon trioxide dissolved in moist acetonitrile. The precipitation in acetonitrile is less dependent on pH, but is more subject to coprecipitation

(2) H. Selig, *Inorg. Chem.*, **5**, 183 (1966).

(3) T. M. Spittler, B. Jaselskis, and J. L. Huston, presented at the 153rd National Meeting of the American Chemical Society, Miami, Fla., April 1967.

of the reagent which is present in excess. The resulting precipitate compares well to the aqueous preparations: infrared spectra and analyses are almost identical.

The chloride in the cesium chloroxenate is determined by Fajans method after the decomposition of xenate with dilute hydrogen peroxide. Cesium is determined either as cesium perchlorate or indirectly as cesium chloride titrimetrically, and the oxidation equivalent is determined iodometrically by "hi-lo" titration. The analyses of chloride, cesium, and oxidation equivalent yield the empirical formula weight 347, 348, and 344, respectively, as compared to the calculated formula weight 346.5 for  $\text{CsClXeO}_3$ .

Cesium chloroxenate is considerably more stable than xenon trioxide. It loses some xenon and oxygen at approximately 150° and on further heating evolution of xenon and oxygen diminishes. At temperatures higher than 190°, xenon and oxygen are evolved rather rapidly and the sample explodes at approximately 205° *in vacuo*, leaving cesium chloride residue. Cesium chloroxenate is shock sensitive and should be handled with care. Cesium chloroxenate, upon addition to concentrated sulfuric acid, yields chlorine, chlorine oxides, oxygen, and xenon.

Crystalline cesium chloroxenate shows a number of infrared bands at 818 (s), 793 (s), 766 (m), 749 (m), 663 (w), and 400 (m)  $\text{cm}^{-1}$ . The strong bands at 818 and 749  $\text{cm}^{-1}$  are similar to cesium fluoroxenate at 807 and 757  $\text{cm}^{-1}$  as reported by Selig.<sup>2</sup> The X-ray powder diffraction pattern is different from cesium chloride and xenon trioxide calculated *d* values.<sup>4</sup> However, the general pattern of lines resembles that of  $\text{CsFXeO}_3$ , as prepared in our laboratory.<sup>3</sup> The *d* spacings for the  $\text{CsClXeO}_3$  are: 4.03 (w), 3.82 (m), 3.34 (m), 3.20 (w), 2.68 (m), 2.34 (m), 2.00 (s), and 1.74 (w) Å. (Some of these weak lines may be due to the decomposition of crystals in the X-ray beam as has been observed in the study of various xenon(VI) compounds.)

We are continuing our investigations on the nature of the halide interactions with xenon trioxide.

## Dibenzoequinene. A Novel Heptacyclic Hydrocarbon from the Photolysis of [2.2]Paracyclonaphthene

Sir:

In a recent communication<sup>1</sup> we reported that [2.2]paracyclonaphthene (I)<sup>2</sup> undergoes photosensitized autoxidation to form the dibenzo dimethoxy polycyclic system II. We have now found that, in the presence of ultraviolet light,<sup>3</sup> I is converted to the novel hydrocarbon IV, "dibenzoequinene."<sup>4</sup>

(1) H. H. Wasserman and P. M. Keehn, *J. Am. Chem. Soc.*, **88**, 4522 (1966).

(2) D. J. Cram, C. K. Dalton, and G. R. Knox, *ibid.*, **85**, 1088 (1963).

(3) In our initial dye-photosensitized autoxidation studies we used a 150-w floodlamp as light source. This was replaced by a sunlamp in order to decrease reaction time and improve yields. Compound IV was observed as a minor product in the photosensitized autoxidations

Ultraviolet irradiation<sup>6</sup> of [2.2]paracyclonaphthene in degassed benzene-methanol (1:1) for 10 days yielded IV (50%), after chromatography on silica gel and recrystallization from hexane. *Anal.*<sup>7</sup> Calcd for  $C_{24}H_{20}$ : C, 93.46; H, 6.54; mol wt, 308. Found: C, 93.53; H, 6.20; mol wt (mass spectroscopy), 308.

The photolysis product did not exhibit a sharp melting point. At about 190–200° a change in the crystalline structure was observed, and melting finally took place: 294–298° dec. (The reported melting point of I is 299–301°.) Examination of the ultraviolet spectrum of material which had been heated to 200° clearly showed that a thermal reversal of IV to I had taken place.

Further spectroscopic examination of product IV revealed the following. (i) The infrared spectrum ( $CHCl_3$ ) contains broad (CH) absorption in the 2800–1000- $cm^{-1}$  range with no bands in the regions associated with alcohol or ether groups. (ii) The mass spectrum (like the spectrum of I) shows only a base peak

carried out in the presence of ultraviolet light, but it was the main product in the purely photochemical reaction in the absence of oxygen. (4) We suggest the trivial name "equinene" for the parent  $C_{16}H_{12}$  bicyclic diene (i) which has not yet been prepared. As has been pointed out earlier,<sup>8</sup> this hydrocarbon would be formed if [2.2]-paracyclonaphthene were to undergo a twofold intramolecular Diels-Alder reaction.

(5) R. C. Helgeson and D. J. Cram, *J. Am. Chem. Soc.*, **88**, 509 (1966).

(6) An air-cooled Rayonet Photochemical Reactor (Southern New England Ultraviolet Co., Middletown, Conn.) and a Pyrex reaction vessel were used. The light source consisted of 16 lamps at 3500 Å.

(7) We thank Dr. Robert Rittner of the Olin Mathieson Chemical Corp. for assistance in obtaining the microanalytical data.

Figure 1. Ultraviolet spectrum of dibenzoequinene (IV) in hexane (---); the dimethoxy polycyclic system (II) in ethanol (—); and *o*-xylene in hexane (-.-).

at  $m/e$  154 and a molecular ion peak at  $m/e$  308, suggesting a hydrocarbon of molecular formula  $C_{24}H_{20}$  which has a high degree of symmetry. (iii) The ultraviolet spectrum of the hydrocarbon (Figure 1) bears a very close resemblance to the spectrum of II, and also to that of *o*-xylene. (iv) The nmr spectrum is remarkably uncomplicated, showing three sharp singlets, in the ratio 2:2:1, at  $\tau$  2.65 (8 aromatic H), 7.60 (8 H at positions a), 8.36 (4 H at positions b). The upfield shift of the four protons at b is in accord with previous observations on the chemical shifts of equatorial hydrogens on the four-membered rings of bicyclo[2.1.1] systems.<sup>8</sup>

The structural representation for the  $C_{24}H_{20}$  hydrocarbon which is clearly in accord with all of the above information is the hydrocarbon IV. This product appears to form by a light-induced intramolecular cyclization<sup>9</sup> possibly through the intermediate III. Other products formed in this photochemical reaction are under investigation.

An independent X-ray structure determination on dibenzoequinene is in progress by Dr. Albert Fratini of the U. S. Naval Research Laboratories, Washington, D. C.<sup>10</sup>

(8) K. B. Wiberg, B. R. Lowry, and B. J. Nist, *J. Am. Chem. Soc.*, **84**, 1594 (1962).

(9) Recent studies on [2.2]paracyclonaphthene have shown that, on irradiation with ultraviolet light, this system undergoes ring opening without formation of i.

(10) NOTE ADDED IN PROOF. Dr. Fratini has recently informed us that he has confirmed structure IV by X-ray analysis.

**Acknowledgments.** This work was supported by Grant GM 13854 from the National Institutes of Health. We wish to thank Drs. S. Lipsky and W. McMurray for help in determining the mass spectra of products formed in this and related work. We also thank B. von Klock for technical assistance.

## Peptide Bond Formation and Subsequent Hydrolysis at a Cobalt(III) Center

Sir:

We wish to report the rapid formation of a peptide bond in nonaqueous solutions at room temperature using the  $\text{Co(trien)}^{2+}$  (trien = triethylenetetramine) moiety as a N-terminal protecting group and as an activating center. This discovery was made during a preparative study of cobalt(III) complexes containing monodentate amino acid amides and esters.

Treatment of  $\alpha$ - or  $\beta$ - $[\text{Co(trien)(TBP)}_2]^{2+}$  or  $\beta$ - $[\text{Co(trien)Cl(glyOEt)}](\text{ClO}_4)_2$  with glycine ethyl ester in dry TBP, and sulfolane or dimethylformamide solutions, respectively, results in the rapid condensation of two glycine ester residues and the formation of the  $\beta$ - $[\text{Co(trien)glyglyOEt}]^{2+}$  ion. The reactions (eq 1–3) are complete within 2 min at 25°.

Chromatography on cation ion-exchange paper (Whatman cellulose phosphate P81) showed almost quantitative formation of the dipeptide ester complex, and analytically pure  $\beta$ - $[\text{Co(trien)glyglyOEt}](\text{ClO}_4)_2 \cdot \text{H}_2\text{O}$  was isolated in high yield (~80%) from each of the reactions. (Anal. Calcd: C, 21.17; H, 4.74; N, 12.35. Found: C, 20.86; H, 4.82; N, 12.16). An identical product was isolated following treatment of  $\beta$ - $[\text{Co(trien)(H}_2\text{O)}_2]^{2+}$  with glycyglycine ethyl ester in aqueous solution at pH 7.5–8.0 for 1 hr at 25° and addition of  $\text{NaClO}_4$  (reaction 4).

The equivalence of the products isolated from reactions 1–4 was established by comparisons of pmr ( $\delta$  1.3 (triplet), 4.36, 4.27, and 4.25 ppm (masked quartet); intensity ratio 3:2:2:2), infrared (1735  $\text{cm}^{-1}$  ester carbonyl, 1630  $\text{cm}^{-1}$  coordinated amide carbonyl), and visible ( $\epsilon_{248}$  153;  $\epsilon_{478}$  141) spectra, as well as by their chromatographic behavior and analytical data. The

(1)  $\alpha$  and  $\beta$  refer to the geometrical arrangement of triethylenetetramine about the metal atom: G. H. Searle and A. M. Sargeson, *Inorg. Chem.*, **4**, 45 (1965). TBP = tri(*n*-butyl) phosphate.

(2) Subscripts  $\beta_1$  and  $\beta_2$  are used to distinguish between the two nonequivalent positions in the  $\beta$  structure; see II and III below.

compound  $\beta$ - $[\text{Co(trien)glyglyOEt}](\text{ClO}_4)_2 \cdot \text{H}_2\text{O}$  is recrystallized without change from neutral or solutions, but undergoes hydrolysis in basic solution (pH  $\geq 8$ ) liberating 1 equiv of glycine ethyl (reaction 5). The resulting glycine chelate  $\beta$ - $[\text{Co(trien)glyglyOEt}](\text{ClO}_4)_2 + \text{OH}^- \longrightarrow$

$\text{gly}]^{2+}$  ion was isolated as its  $\text{I}^-$  and  $\text{ClO}_4^-$  salts (Calcd for  $[\text{CoC}_8\text{H}_{22}\text{O}_2\text{N}_6](\text{ClO}_4)_2 \cdot 0.5\text{H}_2\text{O}$ : C, 14.75; N, 14.38. Found: C, 19.82; H, 14.33) and is identical with that obtained in the action of  $\beta$ - $[\text{Co(trien)(H}_2\text{O)}_2]^{2+}$  with glycine ( $\epsilon_{248}$   $\epsilon_{478}$  134).<sup>2</sup> In view of reactions 4 and 5 and structure I below, it is now proposed that the  $\beta$ - $[\text{Co(trien)glyOEt}]^{2+}$  ion is the intermediate in the hydrolysis of peptide esters and amides catalyzed by the  $\beta$ - $[\text{Co(trien)OH(H}_2\text{O)}]^{2+}$  ion.<sup>4</sup>

An X-ray structural study of  $\beta$ - $[\text{Co(trien)glyOEt}](\text{ClO}_4)_2 \cdot \text{H}_2\text{O}$  establishes its geometrical configuration as I<sup>5</sup> in which glycyglycine ethyl ester func-

as a bidentate ligand by attachment to cobalt through the terminal amino nitrogen and peptide carbonyl oxygen atoms. This, together with the experimental evidence below, establishes the geometrical structure of the hydrolyzed product,  $\beta$ - $[\text{Co(trien)gly}]^{2+}$ , and reaction 5, as II and III, respectively, in agreement with previous assignments.<sup>3</sup>

To establish that formation of the peptide bond occurs at the cobalt(III) center,  $\beta$ - $[\text{Co(trien)Cl(glyOEt)}](\text{ClO}_4)_2$  (1 g) (Anal. Calcd: C, 22.13; H, 5.01; N, 12.91. Found: C, 21.98; H, 5.12; N, 12.99) containing  $\text{C}^{14}$ -labeled glycine ethyl ester ( $4850 \pm 17$  mg of complex) was treated with 2 equiv of freshly prepared inactive glycine ethyl ester (0.4 g) in sulfolane (10 ml) and the reaction quenched after 2 min by addition of ethanol and ether. The  $\beta$ - $[\text{Co(trien)glyOEt}](\text{ClO}_4)_2 \cdot \text{H}_2\text{O}$  obtained after two recrystallizations from hot water (Anal. Calcd: C, 21.17; H, 4.74; N, 12.35. Found: C, 21.25; H, 4.42; N, 12.35) and unreacted glycine ethyl ester recovered by chromatography were analyzed for their  $\text{C}^{14}$  content

(3) L. G. Marzilli and D. A. Buckingham, *Inorg. Chem.*, **6**, 1082 (1967).

(4) D. A. Buckingham, J. P. Collman, D. A. R. Happer, and Marzilli, *J. Am. Chem. Soc.*, **89**, 1082 (1967).

results of  $3890 \pm 10$  cpm/mg and approximately  $200 \pm 50$  cpm/mg, respectively, establish *no significant exchange of coordinated and free ethyl ester has occurred during the reaction.* Formation of the peptide bond must involve coordination of the coordinated ester and must occur on complex. Subsequent hydrolysis of the  $C^{14}$ -labeled  $\beta$ -[Co(trien)glyglyOEt](ClO<sub>4</sub>)<sub>2</sub>·H<sub>2</sub>O at pH  $\approx 10.25^\circ$  and examination of the  $\beta$ -[Co(trien)gly](ClO<sub>4</sub>)<sub>2</sub>·H<sub>2</sub>O isolated from the resulting solution ( $4930 \pm 5$  cpm/mg) shows 96% retention of activity in chelated glycine residue, and indicates a similar situation in the N-terminal glycine of the  $\beta$ -[Co(trien)-glyOEt]<sup>2+</sup> ion. These results are consistent with, but do not unequivocally establish, the following mechanism for peptide formation and subsequent hydrolysis. Formation of the peptide bond prior to coordination is also allowed by the results, but prior coordination of the incoming ester followed by condensation is excluded.

eliminary results indicate that the intermediate condenses with dipeptide esters to give a coordinated peptide ester, which leads to the possibility that this reaction may be useful as a general method for N-terminal addition of integral amino acid residues to peptide esters. Experiments to distinguish between mechanistic possibilities are presently being conducted. Also the scope and versatility of this reaction are being investigated.

### Chlorosilyl Derivatives of Transition Metals and Evidence for a Conformational Effect on Metal Carbonyl Stretching Bands

Sir:

The chemistry of silicon-transition metal compounds has been developed to a much smaller extent than that of germanium, tin, and lead; this situation may result in part from a lack of suitable preparative methods. We reported recently<sup>1</sup> that triphenylsilane, known<sup>2</sup> to react readily with cobalt carbonyl, would react under more vigorous conditions with the carbonyls of manganese and rhenium, affording (C<sub>6</sub>H<sub>5</sub>)<sub>3</sub>SiM(CO)<sub>5</sub> (M = Mn, Re). We now communicate further studies showing that the silane-metal carbonyl reaction is a rather general one, providing a convenient route to new compounds both expected and unexpected. The reactions of trichlorosilane are particularly interesting, and a number are summarized in Table I. Yields vary widely,

Table I. Trichlorosilane Reactions<sup>a</sup>

<sup>a</sup> In sealed tubes in the 100-180° temperature range using excess Cl<sub>3</sub>SiH. <sup>b</sup> Products characterized by elemental analysis and mass spectrum. In several cases other products are formed which have not yet been fully characterized. <sup>c</sup> Kofler hot-stage microscope. <sup>d</sup> In cyclohexane solution.

but the formation of Cl<sub>3</sub>SiMn(CO)<sub>5</sub> is almost quantitative. On the basis of their infrared spectra, the products are structurally analogous to known derivatives of germanium, tin, and lead. It may be noted that silicon-molybdenum and silicon-nickel bonds have not been reported previously.

The trichlorosilyl derivatives of Table I are of interest in view of the numerous compounds of the trichlorostannyl ligand now known. The latter is regarded as a strong  $\pi$  acceptor and a weak  $\sigma$  donor.<sup>3</sup> Strong  $\pi$ -acceptor character for the Cl<sub>3</sub>Sn ligand is also consistent with trends in CO stretching force constants in Cl<sub>3</sub>SnMn(CO)<sub>5</sub> and related compounds, as we have pointed

(3) R. V. Lindsay, Jr., G. W. Parshall, and V. G. Stolberg, *ibid.*, **87**, 658 (1965); G. W. Parshall, *ibid.*, **88**, 704 (1966).

Figure 1. Carbonyl region of the infrared spectrum of  $\text{CH}_3\text{Cl}_2\text{SiFe}(\text{CO})_2\text{C}_6\text{H}_5$ . Precise band positions are 2031, 2022, 1983, and  $1973\text{ cm}^{-1}$  (cyclohexane solution, about 1 mg/ml, 0.5-mm cells).

Figure 2. Carbonyl region of the infrared spectrum of  $\text{Cl}_2\text{SiFe}(\text{CO})_2\text{C}_6\text{H}_5$ . Precise band positions are 2039 and  $1995\text{ cm}^{-1}$  (cyclohexane solution, about 1 mg/ml, 0.5-mm cells).

out.<sup>1</sup> We have now extended the force constant approach to the corresponding  $\text{Cl}_2\text{Si}$  and  $\text{Cl}_2\text{Ge}^4$  compounds and conclude that *there is little difference among  $\text{Cl}_2\text{Si}$ ,  $\text{Cl}_2\text{Ge}$ , and  $\text{Cl}_2\text{Sn}$  as ligands.*<sup>5</sup> We suggest that the  $\text{Cl}_2\text{Sn}$  group is not unique, except for the ease with which it may be generated in reactions with tin(II) chloride.

Reactions with methyldichlorosilane yield methyldichlorosilyl analogs of many of the compounds of Table I. The infrared spectra of these methylsilyl derivatives reveal some unexpected features in the form of "extra" terminal carbonyl bands. The most striking example is provided by  $\text{CH}_3\text{Cl}_2\text{SiFe}(\text{CO})_2\text{C}_6\text{H}_5$ , of which the spectrum is shown in Figure 1. The spectrum of  $\text{Cl}_2\text{SiFe}(\text{CO})_2\text{C}_6\text{H}_5$  is shown in Figure 2 for comparison. Repeated crystallization and fractional sublimation of the methyl derivative does not alter its spectrum, and its molecular weight in cyclohexane is normal (calculated, 291; found (osmometer), 294). Moreover, the nmr spectrum at  $33^\circ$  shows only two sharp peaks at  $\tau$  6.2 and 9.3 in a 5:3 ratio.<sup>6</sup>

The appearance of more than two CO stretching bands for a compound having only two CO groups leads one to postulate that isomers are present. We believe that these are most likely to be the two conformations of the molecule shown in Newman projection as I and II. Rapid interconversion would account for the

simple nmr spectrum. The phenomenon is being studied in greater detail, and a similar effect has been observed in organotin derivatives such as  $\text{CH}_3\text{Cl}_2\text{SnFe}(\text{CO})_2\text{C}_6\text{H}_5$ .<sup>7</sup>

Isomerism of the tautomeric type, involving equilibria between bridged and nonbridged forms, is well established in metal carbonyls and certain of their deriva-

tives.<sup>8</sup> The present communication, however, is the first report of a *conformational* effect on terminal metal carbonyl frequencies.<sup>9,10</sup> The generality of this phenomenon remains to be established, but it should evidently be borne in mind when a choice between structures is being made on the basis of predicted and observed numbers of carbonyl stretching bands.

(9) The doubling of acyl carbonyl frequencies in compounds of the type  $\text{CXH}_2\text{COMn}(\text{CO})_2$  (F. Calderazzo, K. Noack, and U. Scherer, *ibid.*, **6**, 265 (1966)) is entirely analogous to that produced by rotational isomerism in conventional organic ketones.

(10) A referee has drawn attention to the fact that four strong carbonyl bands were observed by R. B. King in the compound  $\pi\text{-C}_6\text{H}_5\text{Fe}(\text{CO})_2\text{Mo}(\pi\text{-C}_6\text{H}_5)$ : *Inorg. Chem.*, **5**, 2242 (1966). This was attributed by King to a kind of *cis-trans* isomerism involving a bidentate  $\pi$ -allyl group. We agree with the referee's suggestion that isomerism in the  $\pi$ -allyl case may arise from a conformational effect very similar to what is suggested here; i.e., in I and II, replace Cl by  $\text{CH}_3$ ,  $\text{CH}_3$  by H, Si by C, and Fe by Mo. This viewpoint implies that the  $\pi$ -allyl group is monodentate in character, presumably with some freedom of rotation about the  $\pi$ -allyl-metal bond.

(4) The compound  $\text{Cl}_2\text{GeMn}(\text{CO})_2$  has been prepared from  $\text{Cl}_2\text{GeH}$  and  $\text{Mn}_2(\text{CO})_{10}$ : A. N. Nesmeyanov, K. N. Anisimov, N. E. Kolobova, and A. B. Antonova, *Bull. Acad. Sci. USSR, Div. Chem. Sci.*, 1284 (1965). We prepared it by reaction of chlorine with  $(\text{C}_6\text{H}_5)_2\text{GeMn}(\text{CO})_2$ , and observe  $\nu(\text{CO})$  at 2130 (m), 2048 (s), 2038 (m)  $\text{cm}^{-1}$  in cyclohexane.

(5) Actual values of the approximate force constants (mdynes/A) are:  $\text{Cl}_2\text{SiMn}(\text{CO})_2$ ,  $k_1 = 16.86$ ,  $k_2 = 17.17$ ,  $k_3 = 0.222$ ;  $\text{Cl}_2\text{GeMn}(\text{CO})_2$ ,  $k_1 = 16.90$ ,  $k_2 = 17.36$ ,  $k_3 = 0.210$ ;  $\text{Cl}_2\text{SnMn}(\text{CO})_2$ ,  $k_1 = 16.91$ ,  $k_2 = 17.31$ ,  $k_3 = 0.204$ . For an explanation of nomenclature and fuller discussion, see ref 1.

(6) Attempts to measure the low-temperature nmr spectrum have not as yet been successful because of the tendency of solutions of the compound to become very viscous at about  $-20^\circ$ .

# Crystal Structure of $\text{HRe}_2\text{Mn}(\text{CO})_{14}$ : Neutral, "Electron-Deficient," Polynuclear Carbonyl Hydride<sup>1</sup>

The reduction of  $\text{Mn}_2(\text{CO})_{10}$  or  $\text{Re}_2(\text{CO})_{10}$  with  $\text{NaBH}_4$  (subsequent acidification) has given rise to an unusual group of polynuclear carbonyl hydrides:  $\text{H}_2\text{Mn}_2(\text{CO})_{12}$ ,<sup>2</sup>  $\text{H}_2\text{Mn}_2(\text{CO})_{12}$ ,<sup>3</sup>  $\text{H}_7\text{B}_2\text{Mn}_2(\text{CO})_{10}$ ,<sup>3</sup> and  $\text{H}_2\text{Re}_2(\text{CO})_{14}$ .<sup>4a</sup> Only one of these complexes,  $\text{H}_7\text{B}_2\text{Mn}_2(\text{CO})_{10}$ , has so far been examined crystallographically,<sup>3</sup> although attempts have been made to reduce  $\text{H}_2\text{Re}_2(\text{CO})_{12}$ .<sup>6</sup> We now wish to report the structure of  $\text{HRe}_2\text{Mn}(\text{CO})_{14}$ ,<sup>4b</sup> which no doubt will be closely related to  $\text{HRe}_2(\text{CO})_{14}$ .<sup>7</sup>

$\text{HRe}_2\text{Mn}(\text{CO})_{14}$  crystallizes in the monoclinic space group  $\text{P}2_1/\text{n}$  (No. 14) with  $a = 9.31$ ,  $b = 15.82$ ,  $c = 10.14$  Å,  $\beta = 106.4^\circ$ ,  $V = 2032$  Å<sup>3</sup>;  $\rho_{\text{obsd}} = 2.64$  g/cm<sup>3</sup> ( $\rho_{\text{calcd}} = 2.68$  g/cm<sup>3</sup> for  $Z = 4$ ,  $M = 820$ ). A single-crystal X-ray crystallographic analysis, based on complete three-dimensional data (Mo  $\text{K}\alpha$ ;  $\sin \theta_{\text{max}} = 25^\circ$ ) was collected with a Buerger automated diffractometer, and to the location of all nonhydrogen atoms. The R index discrepancy is  $R_F = 10.39\%$  for the 2100 unique reflections. The over-all geometry of the molecule is shown in Figure 1. The metal atoms are in a bent configuration, the Re...Re-Mn angle is  $98.1^\circ$ . The Re-Mn bond length of 2.960 Å is in agreement with the value of 2.97 Å predicted for the M-M distances in  $\text{M}_2(\text{CO})_{10}$  (Mn-Mn = 2.97 Å, Re-Re = 3.02 Å). However, the Re...Re distance of 3.39 Å in  $\text{HRe}_2\text{Mn}(\text{CO})_{14}$  is  $\sim 0.37$  Å longer than a normal Re-Re single bond. It is proposed that a hydrogen atom known<sup>10</sup> to be present in  $\text{HRe}_2(\text{CO})_{14}$  occupies a bridging position between the two rhenium atoms. The otherwise normal octahedral coordination of the rhenium atoms leads us to believe

Figure 1. The stereochemistry of  $\text{HRe}_2\text{Mn}(\text{CO})_{14}$ .

that the Re-H-Re bridge is probably linear [a similar scheme has been suggested for the  $\text{HCr}_2(\text{CO})_{10}^-$  ion<sup>11</sup>]. If a symmetrical, linear Re-H-Re linkage is assumed, then the resulting Re-H distance of 1.695 Å is in remarkably good agreement with the Re-H distance of  $1.68 \pm 0.01$  Å determined by a neutron-diffraction study<sup>12</sup> of  $\text{K}_2\text{ReH}_2$ .

An interesting observation in the present study is that the carbonyls in the  $(\text{OC})_4\text{Re-Mn}(\text{CO})_6$  portion of the molecule are in a strictly staggered conformation (as are those in  $\text{Mn}_2(\text{CO})_{10}$ ,<sup>8</sup>  $\text{Cr}_2(\text{CO})_{10}$ ,<sup>13</sup> and, presumably, the isomorphous<sup>9</sup>  $\text{Re}_2(\text{CO})_{10}$ ), whereas the carbonyl groups in the hydrogen-bridged portion of the molecule are in an eclipsed configuration. (The author's drawing of the  $\text{HCr}_2(\text{CO})_{10}^-$  ion<sup>11</sup> indicates that this too adopts an eclipsed configuration.) Furthermore, the sets of radial carbonyl groups in the  $(\text{OC})_6\text{Mn-Re}(\text{CO})_4$  moiety bend slightly toward each other, a feature noted also for  $\text{Mn}_2(\text{CO})_{10}$ <sup>8</sup> and  $\text{Cr}_2(\text{CO})_{10}$ .<sup>13</sup>

The structure of  $\text{HRe}_2\text{Mn}(\text{CO})_{14}$  taken together with the chemistry (treatment of this compound with CO gives  $\text{HRe}(\text{CO})_6$  and  $\text{MnRe}(\text{CO})_{10}$ )<sup>4</sup> suggests a description of the bonding which correlates the two. The  $\text{HRe}(\text{CO})_6$  unit might be regarded as a neutral ligand in a radial position on  $\text{LMnRe}(\text{CO})_6$ , held through hydrogen bridging *via* a two-electron three-center bond.<sup>14</sup> More extensive studies on  $\text{HRe}_2(\text{CO})_{14}$  strengthen this idea: <sup>13</sup>CO-enriched CO reacts with  $\text{HRe}_2(\text{CO})_{14}$  to produce  $\text{Re}_2(^{13}\text{CO})_8(^{13}\text{CO})_2$ , with the <sup>13</sup>CO group in the radial position.<sup>15</sup>  $\text{CH}_3\text{CN}$  and  $(\text{C}_6\text{H}_5)_3\text{P}$  similarly give monosubstituted derivatives  $\text{LRe}_2(\text{CO})_6$ , but with  $(\text{C}_6\text{H}_5)_3\text{P}$  axial substitution is observed.<sup>16</sup>

The concept of a neutral transition metal hydride acting as a ligand in metal complexes suggests the formulas of a large class of electron-deficient polynuclear metal hydrides. A few such possibilities based on known complex hydrides and known carbonyls would be:  $(\text{OC})_6\text{ReH}\cdot\text{M}(\text{CO})_6$  and  $(\pi\text{-C}_5\text{H}_5)_2\text{ReH}\cdot\text{M}(\text{CO})_6$  (M = Cr, Mo, W),  $(\text{OC})_4\text{CoH}\cdot\text{Fe}(\text{CO})_4$ , or  $\text{L}_2(\text{X})\text{PtH}\cdot\text{M}(\text{CO})_{n-1}$  [where  $\text{M}(\text{CO})_n$  is any of a number of known carbonyls]. These compounds would be

related by loss of a proton to the corresponding polynuclear carbonyl anions<sup>17</sup> and could, therefore, in some cases be very strong proton-releasing acids. The electron-deficient polynuclear carbonyl hydrides would also be isoelectronic with polynuclear protonated metal carbonyl species such as  $(\pi\text{-C}_5\text{H}_5)(\text{CO})_2\text{FeHMn}(\text{CO})_5^+$  or  $(\pi\text{-C}_5\text{H}_5)(\text{CO})_2\text{WHW}(\text{CO})_2(\pi\text{-C}_5\text{H}_5)^+$  reported by Wilkinson and co-workers.<sup>18</sup> The question of the placement of the hydrogen atoms is the same in these two classes of compound.

## The Total Synthesis of Racemic Genipin

Sir:

Since the pioneering work of Schmid on the structure of plumieride,<sup>1</sup> the group of monoterpenes containing part structure 1 has rapidly expanded. The suggestion<sup>2</sup> that such compounds are intermediates in the biosynthesis of indole alkaloids has recently been supported by preliminary experiments<sup>3</sup> which, however, need confirmation with multiply labeled compounds. Until now no member of this class of natural products has been prepared from the elements, but the present communication reports on a synthesis of genipin (2).<sup>4</sup>

The bicyclic ethyl ester 3<sup>5-7</sup> on base hydrolysis was transformed to the acid 4, mp 53–55° (lit.<sup>8</sup> mp 51–52°). Reduction with lithium in liquid ammonia followed by esterification with methanol in the presence of *p*-toluenesulfonic acid afforded a mixture of methyl esters containing approximately 90% of 5.

When the diene 5 was treated with osmium tetroxide in dimethylformamide and the resulting osmate ester cleaved with hydrogen sulfide,<sup>9</sup> a crystalline tetrol (6), mp 163–165°, was formed in 50% yield. Although

this material was a mixture of two epimers it was directly for further transformation. Taking advantage of earlier work which demonstrated that *cis*-cyclopentane-1,2-diols are cleaved much more rapidly than *cis*-1,2-cyclohexanediols,<sup>10</sup> a mixture of tetrols 6 was exposed to 1 equiv of the agent in glacial acetic acid solution. Oxidation complete within seconds and chromatography of the resulting mixture of products gave three triols: [11%; mp 156–157°; infrared absorptions (KBr) 3550, 1700, 1640 cm<sup>-1</sup>; ultraviolet absorption (EtOH) 240 mμ (ε 10,500), in 0.01 *N* NaOH 273 (ε 19,000)], 7b [12%; mp 176–177°; infrared absorptions (KBr) 3500, 3355, 1690, 1635 cm<sup>-1</sup>; ultraviolet absorptions same as those of 7a], and 7c [22%; mp 202–208°; infrared absorptions (KBr) 3425, 1690, 1635 cm<sup>-1</sup>; ultraviolet absorptions same as those of 7a]. Investigations aimed at clarifying configurations of the three triols 7 are incomplete. Isomers 7a and 7b on consecutive treatments with tone and with dicyclohexylcarbodiimide–dimethyl oxide<sup>11</sup> yielded the same lactone, 8, mp 109–110° having infrared and ultraviolet absorptions identical with those of 7a. This tentatively indicates that the triols differ only in the configuration of the hemiacetal carbon atom. Triol 7c did not yield an acetone derivative quantitatively cleaved by periodic acid.

The resulting crude dialdehyde was cyclized by the agency of piperidine acetate,<sup>12</sup> and the desired bicyclic aldehyde 9 was obtained in 68% yield in the form of a liquid with infrared absorptions (CHCl<sub>3</sub>) at 2800, 1670, 1630 cm<sup>-1</sup>. Reduction of the aldehyde 9 with lithium tri-*t*-butoxyaluminumhydride<sup>13</sup> in ether afforded racemic genipin (2), mp 116–117°. Identity with natural genipin<sup>14</sup> was established by comparison of infrared

### Rescence of Iridium(III) Chelates with 2,2'-Bipyridine and with 1,10-Phenanthroline

A few complexes of transition metal ions having partially filled d shell are luminescent in fluid solutions. A notable exception is the tris(1,10-phenanthroline)iridium(II) ion; this species and several other Ru(II) complexes with some similar ligands were first reported to luminesce by Brandt and co-workers.<sup>1,2</sup> Paris and Itt<sup>3</sup> assigned the bands in the absorption spectrum of the tris(2,2'-bipyridine)ruthenium(II) ion and concluded that the emission accompanied a ligand-to-metal charge-transfer ( $\pi^* \rightarrow d$ ) transition. Later, weak absorption bands at 539 m $\mu$  (18.550 kK) and at 664 m $\mu$  (10 kK) were reported for the latter species and led to assignment of the luminescence as fluorescence associated with a ligand-field ( $^1T_1 \rightarrow ^1A_1$ ) radiative transition.<sup>4</sup> More recently other workers have concluded that there is no compelling reason to assign the luminescence of the tris(2,2'-bipyridine)ruthenium(II) to a ligand-field transition; indeed, there are several reasons against such an assignment.<sup>4</sup>

The present work describes luminescence from fluid solutions of the analogous iridium(III) chelates: 2,2'-bipyridineiridium(III) ion, [Ir(bipy)<sub>3</sub>]<sup>3+</sup>, and 1,10-phenanthrolineiridium(III) ion, [Ir(phen)<sub>3</sub>]<sup>3+</sup>. The group theoretical classification of these chelates is as follows. The metallic ion is in an octahedral environment; however, these species are diamagnetic: the metallic ion has the low-spin d<sup>6</sup> configuration and geometry analogous to the ruthenium(II) chelates. The emission is expected to accompany charge-transfer transitions from ligand to the metal ion ( $\pi^* \rightarrow d$ ), i.e., similar in kind to those assigned by Paris and Brandt for the luminescence of the Ru(II) chelates.<sup>1</sup>

The ultraviolet-visible absorption spectra for the above species are shown in Figure 1. The absorption spectrum of 2,2'-bipyridine in concentrated sulfuric acid is included in Figure 1 because the diprotonated

Figure 1. Absorption and luminescence spectra: (1) [Ir(bipy)<sub>3</sub>]<sup>3+</sup> absorption spectrum in DMF; (2) [Ir(bipy)<sub>3</sub>]<sup>3+</sup> luminescence spectrum in DMF, 370-m $\mu$  excitation; (3) [Ir(phen)<sub>3</sub>]<sup>3+</sup> absorption spectrum in DMF; (4) [Ir(phen)<sub>3</sub>]<sup>3+</sup> luminescence spectrum in DMF, 475-m $\mu$  excitation; (5) 2,2'-bipyridine absorption spectrum in concentrated H<sub>2</sub>SO<sub>4</sub>.  $I_L$  = luminescence intensity (in arbitrary units and corrected for variation of detector response with wavelength).

form most nearly approximates chelated 2,2'-bipyridine with respect to the energies of the intraligand ( $\pi^* \leftarrow \pi$ ) transitions. Assignments of the absorption bands are given in Table I.

Table I. Absorption Band Assignments for 2,2'-Bipyridine and 1,10-Phenanthroline Chelates of Ir(III)

Compound	$\lambda_{\max}$ , m $\mu$ <sup>a</sup>	Log $\epsilon$ <sup>b</sup>	Assignment
2,2'-Bipyridine <sup>c</sup>	285	4.83	$\pi^* \leftarrow \pi$
	235	4.89	$\pi^* \leftarrow d$
	284	5.08	$\pi^* \leftarrow \pi$
	370 (s)	3.2	$\pi^* \leftarrow d$
	480 (s)	2.8	$\pi^* \leftarrow d$
[Ir(bipy) <sub>3</sub> ] <sup>3+</sup> <sup>d</sup>	515 (s)	2.3	$\pi^* \leftarrow d$
	<300	>4.7	$\pi^* \leftarrow \pi$
	310 (s)	4.4	$\pi^* \leftarrow \pi$
	350 (s)	3.7	$\pi^* \leftarrow d$
	430 (s)	2.7	$\pi^* \leftarrow d$
	520 (s)	2.1	$\pi^* \leftarrow d$

<sup>a</sup> s = shoulder. <sup>b</sup>  $\epsilon$  is molar absorptivity. <sup>c</sup> Solvent, concentrated H<sub>2</sub>SO<sub>4</sub>. <sup>d</sup> Solvent, dimethylformamide.

Jørgensen attributed bands in the range 285-345 m $\mu$  in the absorption spectra of 20 Ir(III)-pyridine complexes to ( $\pi^* \leftarrow d$ ) charge-transfer transitions.<sup>5</sup> Spectral studies of the tris(ethylenediamine)iridium(III) ion, [Ir(en)<sub>3</sub>]<sup>3+</sup>, in solution show the lowest energy singlet  $d^* \leftarrow d$  ( $^1T_1 \leftarrow ^1A_1$ ) transition at 249 m $\mu$  and the lowest energy triplet ( $^3T_1 \leftarrow ^1A_1$ ) transition at 302 m $\mu$ .<sup>6</sup> Both 2,2'-bipyridine and 1,10-phenanthroline are placed above ethylenediamine in the spectrochemical series.<sup>7</sup> Therefore, in [Ir(bipy)<sub>3</sub>]<sup>3+</sup> and [Ir(phen)<sub>3</sub>]<sup>3+</sup> the splitting of the several ligand field states will be larger than in [Ir(en)<sub>3</sub>]<sup>3+</sup>, and more energy will be required to effect the  $^1T_1 \leftarrow ^1A_1$  and  $^3T_1 \leftarrow ^1A_1$  transitions. The energy required for a ligand-field transition in the 2,2'-bipyridine and 1,10-phenanthroline chelates of Ir(III) is estimated as approximately equal to the energy necessary for an intraligand ( $\pi^* \leftarrow \pi$ ) transition and thus is greater than that for a charge-transfer ( $\pi^* \leftarrow d$ ) transition. The luminescence of these Ir(III) chelates is therefore assigned to a  $\pi^* \rightarrow d$  transition.

Spectra of these Ir(III) complexes were obtained in dimethylformamide (DMF) and in ethyl alcohol solution. Solutions were prepared by dissolving the solid chelates  $[\text{Ir}(\text{bipy})_2(\text{ClO}_4)_2]$ , was prepared as previously described;<sup>8</sup>  $[\text{Ir}(\text{phen})_2(\text{ClO}_4)_2]$  was prepared in an analogous manner] and also by heating the stoichiometric amounts of the ligand and the metal ion (from iridium chloride) in refluxing ethyl alcohol for 96 hr or in refluxing DMF for 48 hr. Wavelengths of maximum absorption and emission of these Ir(III) chelates did not depend on the method of preparation or on the solvent. Relative luminescence quantum yields for the chelates (in DMF) were about an order of magnitude less than quinine fluorescence in 0.1 *N*  $\text{H}_2\text{SO}_4$ ; the intensity of  $[\text{Ir}(\text{phen})_2]^{3+}$  was approximately twice the intensity of  $[\text{Ir}(\text{bipy})_2]^{3+}$ .

# Reaction of Tropone with Benzyne. Formation and Photoisomerization of 6,7-Benzobicyclo[3.2.2]nona-3,6,8-trien-2-one

Sir:

As a vinylog of norbornadiene the bicyclo[3.2.2]nona-2,6,8-triene system and its unknown keto derivative I ("homobarrelenone") have elicited recent synthetic interest.<sup>1</sup> We wish to report the practical one-step synthesis of 6,7-benzobicyclo[3.2.2]nona-3,6,8-trien-2-one (II) by thermal addition of benzyne to tropone, and describe herewith a photochemical rearrangement of this adduct.

The thermal decomposition of a suspension of ~40 mmoles of *o*-benzenediazoniumcarboxylate<sup>2</sup> in a solution of 38 mmoles of tropone<sup>3</sup> in anhydrous tetrahydrofuran at 36–37° under nitrogen for 17 hr produced after solvent removal a dark oil. Chromatography over magnesium silicate (benzene–ether) afforded a colorless crystalline adduct in 40% yield,<sup>6,7</sup> purified by sublimation under reduced pressure (50–60°, 0.10 mm) or recrystallization from hexane, mp 83–84°. Structure II is assigned on the basis of the following data: mass

(1) M. J. Goldstein and A. H. Gevirtz, *Tetrahedron Letters*, 4413 (1965).

(2) The benzyne intermediate was generated *in situ* according to the Friedman<sup>3</sup> modification of the Stiles<sup>4</sup> procedure.

(3) L. Friedman, private communication.

(4) M. Stiles, R. G. Miller, and U. Burkhardt, *J. Am. Chem. Soc.*, **85**, 1792 (1963).

(5) P. Radlick, *J. Org. Chem.*, **29**, 960 (1964).

(6) A second uncharacterized product, isolated from the hexane–benzene eluates, was shown to be a 2:1 benzyne–tropone adduct by mass spectrometry (*m/e* 258).<sup>7</sup>

(7) The chromatographic medium used was Florisil synthetic adsorbent, a product of the Floridin Co.

Table I. Nuclear Magnetic Resonance Data

Positional assignment <sup>a</sup>	Chemical shift, ppm from TMS	Coupling constants, cps

irradiation of adduct II by a medium-pressure mercury lamp (glass filter, acetonitrile solvent, 20°, open atmosphere) resulted in the gradual formation of a carbonyl maximum near 1704  $\text{cm}^{-1}$  with a concomitant decrease in the original carbonyl peak at 1675  $\text{cm}^{-1}$ . Silica gel chromatography of the reaction products, followed by sublimation at 80° of the principal chromatographic fraction, gave a new crystalline compound: mp 119–120°; mass spectrum:  $m/z$  182, 153, 126, 76;  $\nu_{\text{max}}^{\text{CHCl}_3}$  1707  $\text{cm}^{-1}$ ;  $\lambda_{\text{max}}^{\text{CH}_3\text{OH}}$  250 ( $\epsilon$  61,800), 274 (8700), 284 (10,200), 296 (6600), 2930, 342 (3250); nmr spectrum:  $A_2B_2$  pattern with  $\delta_A$  2.85,  $\delta_B$  3.32, and an aromatic multiplet at  $\delta$  7.5–8.2. *Anal.* Calcd for  $C_{13}H_{10}O$ : C, 85.70; H, 5.3; mol wt, 182. Found: C, 85.99; H, 5.75. Consistent with the fact that sodium borohydride reduction of the photoproduct generated the ultraviolet spectrum of 1,2-dialkyl-naphthalene, the above data require the photoproduct to contain a conjugated ketone within a six-membered ring fused to the naphthalene nucleus.

Three such ketones are possible; all are known except isomer IV (lit. mp 120–121°) is compatible with the observed melting point. Moreover, the highly conjugated ultraviolet spectrum of the photoproduct is impossible with that depicted for authentic ketone V and identity was confirmed by comparison with an authentic sample.

IV

V

It can be shown spectroscopically that ketone IV is present in the photolysis solution during irradiation and can be instantly generated therein by addition of base.

We propose that the primary step in the photorearrangement is the rearrangement of II to the diolefinic intermediate V,<sup>12</sup> with ultimate isomerization to the aromatic ketone V during the work-up procedure. Further studies of the ground-state and excited-state chemistry and its derivatives are in progress.

R. Huisgen and U. Rietz, *Tetrahedron*, **2**, 274 (1958). We are indebted to Professor Huisgen for providing us with a sample of ketone V prepared by Friedel-Crafts cyclization of  $\beta$ -(1-naphthyl)propionic acid.

The photoequilibrium between 1,4,4-trimethylbicyclo[3.2.0]hept-2-one and 4,4,6-trimethylbicyclo[3.2.0]hept-6-en-2-one described by G. Büchi and E. M. Burgess (*J. Am. Chem. Soc.*, **82**, 4333 (1960)) may offer formal analogy to this type of isomerization.

## Hofmann Elimination. I. An Example of a *cis*-E2 Mechanism<sup>1</sup>

Hofmann elimination of quaternary ammonium hydroxides to give olefins has long been thought to proceed by a *trans* elimination.<sup>2</sup> Only two proven exceptions to this have been reported. One of these involves a *cis*-E2 elimination of N,N,N-trimethyl-*trans*-2-phenylcyclohexylammonium hydroxide to give 1-phenylcyclohexene.<sup>3</sup> This *cis* elimination presumably takes place because of the activating influence of the phenyl group on the  $\beta$  proton (increased acidity). The other exception involves a predominantly *cis*-ylide elimination of N,N,N-trimethyl-2-*t*-butyl-3,3-dimethylbutylammonium-2-*d*<sub>1</sub> hydroxide to give trimethylamine-*d*<sub>1</sub>.<sup>4</sup>

We wish to report an example of a *cis*-E2 elimination mechanism involving a trimethylammonium hydroxide in which there is no activating group other than the trimethylammonium group. It has been shown<sup>5</sup> that N,N,N-trimethyl-*exo*-2-norbornylammonium hydroxide is smoothly converted to norbornene on heating. We have examined this reaction and find that it proceeds by a *cis*-E2 elimination, as deduced from the following evidence. 2-*exo*-Norbornylamine-3-*exo*-*d*<sub>1</sub> (bp 159–163° (760 mm);  $n_D^{20}$  1.4752; acetamide mp 141.5–142.5°) was prepared from norbornene using diborane-*d*<sub>6</sub> and chloramine<sup>6</sup> and was then converted consecutively by standard procedures to N,N-dimethyl-2-*exo*-norbornylamine-3-*exo*-*d*<sub>1</sub> (bp 50–52° (6 mm);  $n_D^{20}$  1.4690), N,N,N-trimethyl-2-*exo*-norbornylammonium-3-*exo*-*d*<sub>1</sub> iodide (mp 297–299°), and then to the hydroxide 1. Compound 1 was heated (as the dry solid) at 120° under vacuum until trimethylamine could just be detected in the vapors. This initially produced trimethylamine was analyzed by mass spectrometry<sup>7</sup> and was found to contain 6% trimethylamine-*d*<sub>1</sub>. When the pyrolysis was carried to completion the total trimethylamine was found to contain 17% trimethylamine-*d*<sub>1</sub>, with the last traces of vapors containing 21% trimethylamine-*d*<sub>1</sub>. This increase in incorporation of deuterium into the trimethylamine after the initial stages of the reaction has been studied by Cope and co-workers<sup>8</sup> and is due to exchange between the methyl hydrogens of the quaternary hydroxide and the water (containing some deuterium) produced during the reaction. In another experiment the pyrolysis of 1 was carried to completion and the norbornene (2) that was formed was purified and examined by nmr and mass

spectrometry. Integration of the nmr spectrum (using the C-7-methylene protons as an internal standard) indicated the norbornene (2) contained no deuterium, and the mass spectrum confirmed this. All compounds up through the hydroxide 1 were shown to contain one deuterium/molecule by mass spectrometry and nmr spectroscopy.

The fact that the trimethylamine formed from the initial stages of Hofmann elimination of 1 contains 6% trimethylamine- $d_1$  indicates this reaction proceeds to the extent of not more than 6% by an ylide mechanism. The remaining 94% of the reaction proceeds by some other reaction path, and this can be determined by the following arguments. An E1cb mechanism in this case is unlikely.<sup>3</sup> Equilibration of 1 to give the corresponding *endo* isomer followed by *trans* elimination is also ruled out since it has been shown that the *endo* isomer gives only a trace of norbornene.<sup>5</sup> The only remaining possible mechanism is thus a *cis*-E2 elimination, and this mechanism accounts for 94% of the reaction product. This is analogous to dehydrohalogenations of 2,3-dihalonorbornanes.<sup>9</sup>

The factors affecting this reaction, its occurrence in aliphatic and other alicyclic systems, and the effect of solvents on the mechanism of the reaction will be examined in a full paper.

## Polar Additions to Olefins and Acetylenes.

### IV. Evidence for Synchronous C-H and C-Cl Bond Formation in the *trans* Addition of Hydrogen Chloride to 3-Hexyne<sup>1</sup>

Sir:

A somewhat confusing picture has developed regarding the stereochemistry of acid additions to acetylenes. These additions were once thought to be stereospecific *trans* processes based on studies of acetylenecarboxylic acid derivatives,<sup>2</sup> but recent studies have shown that 3-hexyne adds trifluoroacetic acid nonstereospecifically<sup>3</sup> and that the hydrochlorination of 1-phenylpropyne in acetic acid yields a mixture of *cis* and *trans* adducts.<sup>4</sup> Nonstereospecific addition is readily understood if vinyl cations 1 are formed as intermediates in these additions, and for additions in polar media there is substantial evidence<sup>5</sup> to support this hypothesis. The factors leading to stereospecific *trans* addition are less clear. One possibility is that a slow protonation leads to a bridged cation (or  $\pi$  complex) 2 which then collapses rapidly to *trans* adduct. Another explanation, analogous to that pro-

posed by Hammond<sup>6</sup> for olefins, is that *trans* addition occurs *via* transition state 3 in which the C-H and C-X bonds are simultaneously formed. We report here studies of the hydrochlorination of 3-hexyne in acetic acid which show that *trans* addition can occur *via* the latter process.

The hydrochlorination of 3-hexyne in acetic acid yields 3-chloro-*trans*-3-hexene<sup>7</sup> (4), 3-chloro-*cis*-3-hexene (5), and 3-hexanone (6), the latter undoubtedly formed *via* the intermediate vinyl acetate.<sup>4,8</sup> The reaction was

followed by quenching samples of the reaction mixture in water, extracting three times with pentane, and analyzing the pentane fraction by vpc. Control experiments showed that 4, 5, and 6 are stable under the reaction conditions, that no fractionation occurs in the work-up, and that 4, 5, and 6 comprise >95% of the total product. The reaction was studied in the presence and absence of tetramethylammonium chloride (TMAC), and initial rates, *R*, for total product formation and product compositions were determined at less than 10% conversion. The results are presented in Table I. To these may be added the observations that, in the absence of both TMAC and HCl or in the presence of TMAC and absence of HCl, no reaction occurs.

Table I. The Hydrochlorination of 3-Hexyne in Acetic Acid at 25.0°\*

Under identical reaction conditions the steric course of addition to 1-phenylpropyne and to 3-hexyne is strikingly different: 1-phenylpropyne yields a mixture of adducts with the *cis* hydrochloride predominating, while 3-hexyne gives nearly equal amounts of ketone and *trans* hydrochloride but only a trace of *cis* hydrochloride. It is found that 3-hexyne reacts about three-

more slowly than 1-phenylpropyne.<sup>4</sup> The ratio chloride to ketone is found to increase substantially with the HCl concentration for 3-hexyne but was shown to undergo no significant change for 1-phenylpropyne.<sup>4</sup> These observations indicate that a different mechanism exists for addition to 3-hexyne than for 1-phenylpropyne.

The results in Table I show, TMAC greatly enhances the rate of formation of *trans* chloride but has little effect on the rate of formation of ketone. At 25°C the rates for product formation can be expressed approximately as

$$[4]/dt = kA[\text{HCl}]^{2.6} + k'A[\text{TMAC}][\text{HCl}]^{1.4}$$

$$d[6]/dt = k''A[\text{HCl}]^{1.3}$$

where  $A$  is the concentration of 3-hexyne. The numerical values of the rate constants for these expressions are probably not meaningful since it is not yet clear whether fractional orders in HCl should be associated with changes in the solvent character at the high concentrations employed here or with rate expressions involving second-, and third-order terms in HCl. In either case it is clear that chloride formation in the absence of TMAC is associated with a rate equation approximately of order higher in HCl than that for ketone formation in the TMAC-catalyzed reaction. These results are unexpected for a mechanism involving the formation of a cationic intermediate but are in accord with a mechanism involving synchronous formation of the C-X and C-C bonds.

This mechanism can be formulated as shown in Scheme I. Since acetylenes<sup>9</sup> and other unsaturated carbons<sup>10</sup> are known to form weak complexes with HCl, the first step in the reaction is postulated as a reversible complex formation. Competing at-

on the complex by HCl, TMAC, and HOAc leads to transition state 7, to *trans* adduct. The vinyl chloride is then rapidly converted to ketone. The fractional order in HCl may result from solvation of the charge-separated transition state 7 or from competing reactions in which hydrogen dichloride ion, rather than chloride ion, is produced in the rate-limiting step.

The results show that, in the apparent rate equation,  $k'$  is over 100 times larger than  $k$ , which is consistent with TMAC being a better nucleophile than

the observation that 3-hexyne in refluxing trifluoroacetic acid undergoes nonstereospecific addition<sup>8</sup> suggests that the stepwise vinyl cation mechanism and the synchronous mechanism are both accessible for addition to 3-hexyne depending upon the reaction conditions.

Trifluoroacetic acid, being polar and strongly acidic but weakly nucleophilic, should favor addition *via* a vinyl cation intermediate. There is, in fact, evidence suggesting that a vinyl cation mechanism may be competitive with the synchronous process for the hydrochlorination in acetic acid. Thus, although chloride 5 is a negligible product for addition at 25°C, we find that at 80°C it amounts to 5% of the total reaction product under kinetically controlled conditions. The present study is being extended to lower acid concentrations and higher temperatures in order to further delineate this apparent competition between stepwise and synchronous addition mechanisms.

## Synthesis of Allenes by Means of Cycloelimination Reactions

Sir:

Although cycloeliminations of the type shown in equation 1 would be of synthetic and theoretical interest, no such reactions have been recorded in the literature. We wish to report the first examples of this type of reaction.

When an ethereal solution of 4-keto-3,3,5,5-tetramethylpyrazoline hydrazone<sup>1</sup> (1) was treated at room temperature, under nitrogen, with a 10-20% molar excess of nickel peroxide,<sup>2</sup> a transient yellow color was formed and vigorous nitrogen evolution ensued, ceasing after *ca.* 10 min. Analysis of the colorless supernatant by glpc<sup>3</sup> indicated the presence of tetramethylallene (2) in yields of 87-91% (eq 2). Freshly prepared silver(I) oxide is less effective, allene 2 being produced in poor (2.5-3.5%) yield. The tetramethylallene thus produced was identified by comparing its glpc retention times (three different columns) and its infrared, nmr, and mass spectra with those of authentic tetramethylallene. Solutions of the intermediate diazo compound 3 are stable at 0°C for at least 30 min, 3 being detectable by its yellow color and by the presence of a strong infrared diazo absorption<sup>4</sup> (2075 cm<sup>-1</sup> in *n*-decane; 2060

(1) W. L. Mock, Ph.D. Thesis, Harvard University, Cambridge, Mass., Sept 1964. A referee has suggested that, owing to the general inaccessibility of this thesis, the general procedures developed by Mock for the preparation of 1 and 4 be outlined. The 4-keto-3,3,5,5-tetramethylpyrazoline precursor of 1 is obtained from the hypobromite oxidation of the 2,4-diamino ketone resulting from reduction of 2,4-diazido-2,4-dimethyl-3-pentanone with hydrogen sulfide. The diazide may be prepared from the corresponding dibromo ketone [A. Favorsky and A. Umnova, *J. Prakt. Chem.*, **88**, 679 (1913)]. Compound 4 may be prepared from the corresponding ketone which is obtained from the peracetic acid oxidation of the known 2,2,4,4-tetramethyl-3-thietanone [G. Claesson, A. Thalén, and L. Schotte, *Arkiv Kemi*, **21**, 295 (1963)].

(3) Glpc analysis was done on an Aerograph A 90-P3 gas chromatograph using a 5 ft × 0.25 in. column of 20% SE-30 on 60-80 mesh Chromosorb W. Both tetramethylallene and toluene, the internal standard used for the yield determinations, are stable to nickel peroxide under the reaction conditions.

D. Cook, Y. Lupien, and W. G. Schneider, *Can. J. Chem.*, **34**, 1569.

H. C. Brown and J. D. Brady, *J. Am. Chem. Soc.*, **71**, 3573

$\text{cm}^{-1}$  in cyclohexene) which fades rapidly if the solution is allowed to warm. Although hydrazone 1 is less soluble in hydrocarbon solvents than it is in ether, the yields of allene 2 are but little affected, averaging ca. 82% in tetramethylethylene and cyclohexene and 77% in *n*-hexane and *n*-decane.

Cycloelimination leading to the formation of tetramethylallene can also be effected when one of the leaving groups is sulfur dioxide (eq 3). When the dry sodium salt, 4, of the tosylhydrazone of 2,2,4,4-tetramethyl-3-thietanone dioxide,<sup>1</sup> prepared by treatment of a tetrahydrofuran solution of the tosylhydrazone with excess sodium hydride, was pyrolyzed *in vacuo* at ca. 110–160° according to the method of Shechter, *et al.*,<sup>5</sup> a 54–56% yield of tetramethylallene was obtained (presumably *via* diazo compound 5) along with sulfur dioxide (identified by its glpc retention time on two different columns and by its infrared spectrum) and sodium *p*-toluenesulfinate (identified by its infrared spectrum).

Preliminary attempts to extend this cycloelimination reaction to the sodium salt of 2,2,4,4-tetramethylcyclobutanedione monotosylhydrazone (elimination of carbon monoxide) have not yielded sufficient tetramethylallene to be detectable by glpc.<sup>6</sup>

Since the two cycloelimination reactions would appear to be mechanistically similar, only the first will be discussed. It is clear that diazo compound 3 is a precursor of allene 2. Whether the two nitrogen molecules are lost simultaneously (pathway a) or stepwise (pathway b) is yet unknown.<sup>7,8</sup> Preliminary attempts

(6) The products of this reaction are under investigation. See G. Maier and M. Strasser, *Tetrahedron Letters*, 6453 (1966), and references cited therein, for the pyrolysis of similar systems in which cycloelimination does not occur.

(7) For possibly related reactions involving the formation of olefins, see (a) E. J. Corey, F. A. Carey, and R. A. E. Winter, *J. Am. Chem. Soc.*, **87**, 934 (1965); (b) D. M. Lemal and E. H. Baniitt, *Tetrahedron Letters*, 245 (1964).

(8) Allenes and other cumulenes have been synthesized by means of carbenic rearrangements. See (a) W. Kirmse, "Carbene Chemistry,"

to trap carbene 6 with cyclohexene or with tetramethylene have been unsuccessful; high yields of methylallene are obtained in these solvents and trace amounts (<2%) of additional reaction products are detectable by glpc.<sup>9</sup> While failure to trap carbene 6 cannot be used as evidence against its existence, the absence of intramolecular C–H insertion products expected for a dialkylcarbene with available  $\beta$ -hydrogen atoms,<sup>11,12</sup> suggests that carbene 6, if formed, is extremely short-lived, cycloelimination of nitrogen being faster than intramolecular C–H insertion. Possibly pathways a and b may be operative.<sup>13</sup>

Experiments designed to test the generality and the chemical course of this type of cycloelimination reaction are in progress.

## The Rearrangement of Phosphorane Boranes

Sir:

The numerous examples of substituent rearrangement from negatively charged boron,<sup>1</sup> and the previously observed<sup>2</sup> reduction of triphenylphosphine oxide by organoboranes, suggested that phosphorane boranes might undergo similar reactions. Although these 1,3-dipolar adducts are in general sufficiently stable to allow isolation under normal conditions, rearrangement does in fact occur at higher temperatures.

When triphenylphosphinemethyleneborane<sup>3</sup> (refluxed in chlorobenzene (bp 131°) for 40 min, a

ion results which evolves 2 moles of hydrogen mole of I) on treatment with acid.

on refluxing in decalin (bp 185–190°) for 20 min, rearrangement of I is followed by alkyl redistribution of boron component. Triphenylphosphineborane (II), which crystallizes from this solvent on cooling, was obtained in 85% yield. Trimethylborane, swept from reaction vessel by a slow stream of argon, was isolated (in high yield) and identified as the pyridinate. Further analysis of the residual decalin solution indicated that it contained essentially only triphenylphosphine (III).

Triphenylphosphinebenzylideneborane<sup>3</sup> (IV) is similarly rearranged by heating for a short time in chlorobenzene or diglyme, as shown by the formation of benzyl alcohol on oxidation with basic peroxide.<sup>5</sup> When a slurry of IV in decalin is refluxed for 15 min, a resulting clear solution on cooling deposits crystals, which again could be isolated in good yield.

The generality of the rearrangement was extended by finding that both aryl and alkyl groups will migrate in analogous phosphorane boranes. Triphenylphosphinemethylenetriphenylborane<sup>4</sup> (V), heated without solvent to 205°, or in decalin for 15 min, gives crystalline triphenylphosphinetriphenylborane<sup>6,7</sup> (VI), indicating

migration of the phenyl group followed by phenyl-alkyl redistribution. The formation of a benzylidene species was again demonstrated by alkaline peroxide formation of benzyl alcohol.<sup>5</sup>

Evidence has been presented<sup>4</sup> that, unlike borane and triphenylborane, trialkylboranes do not form stable complexes with triphenylmethylenephosphorane. Consequently, the question of possible rearrangement of a trialkylborane adduct (viewed as an especially unstable intermediate) was of particular interest.

The starting material is inert under these conditions; no benzyl alcohol is formed, and the phosphorane borane is recovered in high yield. Lack of reaction may be due to low solubility, as typical phosphonium salts would be expected to react rapidly under these conditions.

G. Wittig and W. Haag, *Chem. Ber.*, **88**, 1654 (1955). In the absence of solvent, this material (impure) sublimes to the top of the reaction vessel. In a separate experiment, VI, prepared by the method of Wittig and Haag,<sup>4</sup> was partially sublimed to give material of depressed melting point. Presumably sublimation occurs via dissociation of this complex, and consequently the sublimed VI is contaminated with free triphenylborane and/or triphenylphosphine.

When methyltriphenylphosphonium bromide (VII) is heated in refluxing triethylborane (bp 94°) or diglyme (bp 165°) with sodium triethylborohydride,<sup>8</sup> hydrogen is evolved with concurrent development of a deep red color. The color disappears after a few minutes of refluxing in either solvent. The formation of *n*-propyl-

diethylborane was demonstrated by vpc.<sup>9</sup>

The reaction of phosphonium salts with sodium borohydride has also been investigated. A mixture of VII and sodium borohydride in diglyme on heating evolves hydrogen (60%), again with development and subsequent disappearance of a deep red color. Benzene is formed directly in a side reaction, along with methyl-diphenylphosphine (VIII)<sup>10</sup> (presumably as the borane adduct).

Benzyltriphenylphosphonium borohydride (IX) (mp 150–154° dec), which is obtained in nearly quantitative yield on mixing aqueous solutions of the phosphonium chloride and sodium borohydride, decomposes in boiling chlorobenzene in an analogous manner.

The mechanism of thermal decomposition of IX is to be contrasted with that of the reaction between the corresponding phosphonium halide and lithium aluminum hydride. The latter proceeds rapidly at room temperature (in diglyme) with negligible gas evolution. Toluene is again formed directly, along with a high yield (>80%) of triphenylphosphine (isolated subsequent to hydrolysis).<sup>11</sup>

The toluene obtained from the triphenylbenzylphosphonium salt (in both the borohydride reaction and the lithium aluminum hydride reduction), as well as the benzene obtained in the reaction of VII, presumably arise *via* hydride attack on positive phosphorus to give intermediate (or transition state) pentavalent phosphorus compounds. Evidence for the formation of a related intermediate pentavalent phosphorus hydride (isolable at low temperature) has recently been presented.<sup>12</sup> Formation of toluene by nucleophilic displacement on carbon would seem to be ruled out by

(12) D. Hellwinkel, *Angew. Chem. Intern. Ed. Engl.*, **5**, 968 (1966).

the fact that no methane is obtained in the reaction of VII.

It is also significant that only trace amounts (<1%) of benzene were formed in the thermal decomposition of IX. The ylide triphenylbenzylidenephosphorane, presumably an intermediate in the borohydride reaction, has been reported<sup>11c</sup> to give benzyldiphenylphosphine on reduction with lithium aluminum hydride. It appears that complex formation between the ylide and generated borane, with subsequent rearrangement, competes more successfully with an alternate cleavage process in the borohydride than in the lithium aluminum hydride reaction.

### The Stereochemistry of the Free-Radical Addition of Thiolacetic Acid to 2-Chloro-4-*t*-butylcyclohexene

Sir:

Contemporary studies of radical-chain additions to cyclohexenes<sup>1</sup> have been directed toward determination of both the *trans/cis* addition stereoselectivity and the conformational preference imparted to both the addition and the displacement steps by use of "conformationally fixed" cyclohexenes.<sup>2–6</sup> Although the additions of thiols are not stereospecific in contrast to those of hydrogen bromide,<sup>2,6</sup> *trans* stereoselectivity with a predominance of *trans*-diaxial addition has been observed.<sup>2–4</sup> In at least one case, the results have been attributed to the intervention of an unsymmetrically bridged thiyl radical which was said to account for ~88% of the reaction pathway.<sup>3</sup> The reported dependence of isomeric adduct (*trans/cis*) composition from 1-halocyclohexenes<sup>7</sup> on the ratio of thiol addenda to olefin was not verified with the 4-substituted cyclohexenes.<sup>2–5</sup>

We wish to report a study of the AIBN-initiated addition of thiolacetic acid to 2-chloro-4-*t*-butylcyclohexene (1). The four possible diastereomeric products were detected and characterized, and reproducible temperature and concentration effects were observed.<sup>8</sup> The results provide significant new data for a more detailed description of the stereochemical course of free-radical additions to cyclohexenes.

Typical runs afforded the following product distributions: 53.2% 2, 5.7% 3, 28.3% 4, and 12.8% 5 in hexane at 63°; 78.7% 2, 1.6% 3, 12.8% 4, and 6.9%

<sup>a</sup> AcSH:olefin. Most solutions were made by adding AcSH to 3 ml of a 1 M solution of 1 in the solvent. <sup>b</sup> Reactions were generally run for 1 hr to 40–60% completion with 5 mole % AIBN. Analyses were by gc; deviations in normalized percentages were  $\pm 1.0\%$  for 2 and 4, and  $\pm 0.5\%$  for 3 and 5. <sup>c</sup> Ultraviolet initiated.

The results unequivocally demonstrate that the relative proportions of adducts vary significantly with changes in the molar ratio of starting materials and with temperature. These variations persisted in solvents of widely different polarity. The ratio of adducts resulting from axial relative to equatorial attachment of the thiyl group in the addition step [(2 + 3)/(4 + 5)] increases with lower reaction temperatures (runs 2–6, 8–11) and with higher molar ratios of thiol (runs 1, 4, 10; 5, 11; 7, 12, 14; 8, 13).

It is reasonable to attribute these *primary* concentration and temperature effects to reversibility of the addition step. Stereoelectronic control leads to preferential axial attack by the thiyl radical, affording intermediate 6, whereas 7 would result from less-favored "equatorial attack."<sup>9</sup> This initial preference is at least 4:1 (run 2) and is probably much higher. Elevated temperatures and low thiol concentration favor reversal and

lation of products from the more stable<sup>9</sup> intermediate 7. On the other hand, low temperature and thiol concentration promote rapid displacement kinetically favored 6. Radical-chain additions of species to 4-*t*-butylcyclohexenes, examined under reaction conditions, lead to decreasing amounts of products with axial-X groups in the following order: RSH > ArSH > AcSH > HSH. Reversibility is important for the former three addenda, as a consequence of the lower stability of alkanethiyl radicals is high transfer rate with ArSH, and especially [Br.

displacement reactions with intermediates 6 and to over-all *trans* stereoselectivity, but that from considerably higher and is enhanced at low temperature and high thiol concentrations. One tempting explanation for preferential *trans*-diaxial addition (to give 2) involves an *unsymmetrically* bridged thiyl radical as previously utilized.<sup>3</sup> However, if a bridged intermediate is dominant in promoting the high 2/3 *trans* ratio, a significant variation in the magnitude of the ratio would be anticipated as the thiol addendum varied. Although additional accurate data are required, it appears that the proportions of adducts 2 to 3 are very similar for most thiols under identical conditions. Furthermore, even *symmetrically* bridged radicals, if such are intermediates, cannot maintain configurational integrity in additions to acyclic dienes.<sup>1</sup>

On the other hand, preferential axial chain transfer has been established for the 4-*t*-butyl-<sup>10</sup> and 1-thiolacyclopentyl-4-*t*-butylcyclohexyl<sup>4</sup> radicals. The vicinal, 1-thiyl substituent of 6 should direct displacement 2 even more toward the axial position, and a bridged thiyl radical is not required.

A surprising observation is that the ratio 4/5 is relatively insensitive to reaction conditions. The "open" intermediate 7 appears to control product distribution; however, it is intriguing to note that *trans* addition is favored over *cis* addition (4/5 ~ 1.8–2.6). Investigations of additions of other thiols to 1- or 2-*t*-butylcyclohexenes have indicated that thiol-acid seems to be unique in providing a 4/5 > 1.<sup>2,3</sup> A possible rationale for this reversal involves the five-membered, bridged intermediate in equilibrium with 7, since this pathway is unavailable to alkyl- and arylthiols. However, a dipolar factor may be contributory, particularly in light of the results

reported for 1-methyl-4-*t*-butylcyclohexene and thiolacetic acid.<sup>4</sup>

In the present case, the observed concentration effect does not involve chair-chair interconversions,<sup>7</sup> but rather comes mainly from reversibility of the addition step complemented by a secondary effect of variable chain-transfer preference with the axial thiyl radical 6.

In the full article we shall elaborate a general scheme to accommodate all available data on the stereochemistry of radical additions of thiols to cyclohexenes. The present report serves to clarify certain existing ambiguities and also emphasizes the need for complete product identification.

### Coordination-Catalyzed Skeletal Rearrangement of 1,4-Dienes

Sir:

Our forthcoming publication<sup>1</sup> describes the addition of  $\alpha$ -olefins to conjugated dienes, to produce high yields of 1,4-dienes. A homogeneous catalyst, prepared *in situ* from the reaction of a bis(tertiary phosphine)nickel(II) salt and an alkylaluminum compound, is employed. In an extension of this work we have investigated the behavior of the 1,4-diene products in the presence of the catalyst species.

3-Methyl-1,4-pentadiene (I, 0.012 mole), bis(tri-*n*-butylphosphine)nickel dichloride (0.001 mole), and diisobutylaluminum chloride (0.004 mole) were mixed in 100 ml of dry deoxygenated toluene. During 90 min at 24°, ca. 53% of I was converted to a mixture of products which included components with vpc retention times corresponding to a 35% yield of 1,4-hexadiene (*trans*:*cis* ratio = 11), a 4% yield of *trans*-2-methyl-1,3-pentadiene, 8% *cis*-3-methyl-1,3-pentadiene, a 15% combined yield of *trans*-3-methyl-1,3-pentadiene and *trans,trans*-2,4-hexadiene, and 3% *trans,cis*-2,4-hexadiene. Two components, ca. 9 and 7%, have not been resolved and identified. The remainder was non-volatile material, presumably oligomers of conjugated C-6 products.

It is apparent that the 3-methyl-1,3-pentadienes are derived from the double bond positional isomerization of I. However, the remaining products arise from skeletal rearrangements. A strong indication that the remaining C-6 conjugated products are derived from 1,4-hexadiene, as the primary rearrangement product, was found when *trans*-<sup>2</sup> and *cis*-1,4-hexadienes<sup>3</sup> were treated separately with the catalyst under the above conditions. During 120 min, 34% of the *trans* isomer was converted to *trans,trans*- and *trans,cis*-2,4-hexadiene (*trans,trans*:*trans,cis* ratio = 2.7) in 87% yield.

It has been suggested that intermediates of type 7 arise by rapid reversible conformational reorganization of an initial twist-boat conformation.<sup>4,5</sup>

F. D. Greene, C. Chu, and J. Walia, *J. Am. Chem. Soc.*, **84**, 2463 (1962); *J. Org. Chem.*, **29**, 1285 (1964).

The major product from the *cis*-1,4-hexadiene was derived from a skeletal rearrangement. In addition to the *trans*,*cis*- and *cis*,*cis*-2,4-hexadienes (*trans*,*cis*:*cis*,*cis* ratio = 4.0) afforded in 22% yield, a 75% yield of *trans*-2-methyl-1,3-pentadiene was obtained, the conversion of the 1,4-hexadiene to products being *ca.* 70%.<sup>4</sup>

The products from all of these reactions were isolated and characterized in experiments in which the concentration of diene precursor was increased by a factor of 9–10 over those described above in order to provide sufficient material with which to work. In general, this led to lower yields of rearranged products. The compounds, after isolation by preparative vpc, were identified by their nmr and/or infrared spectra and by comparison of vpc retention times with those of authentic samples.<sup>5</sup> Proof that the reactions were indeed catalyzed by a species derived from the interaction of diisobutyl-aluminum chloride with bis(tri-*n*-butylphosphine)nickel dichloride in the presence of the dienes was obtained from a series of experiments in which I and the 1,4-hexadienes were mixed independently with the aluminum and the nickel catalyst precursors. In all cases, the 1,4-diene was recovered unchanged.

It appears that all of the characterized C-6 products from the interaction of I with the catalyst arise from two primary reaction paths: (1) the double bond positional isomerization of I, and (2) a skeletal rearrangement of I to afford the 1,4-hexadienes.

Information suggesting the nature of path 2 was obtained from experiments in which I was mixed with the catalyst in the presence of an excess of propylene. Admixture of 41 g (0.52 mole) of I with 81 g (1.9 moles) of propylene and the catalyst precursors (Al:Ni = 6:1, mmols) in 400 ml of toluene for 19 min in the 86–90° range (same conditions as utilized for the codimerization of propylene and butadiene to give 2-methyl-1,4-hexadiene<sup>1</sup>) afforded a 9% yield of *trans*-2-methyl-1,4-hexadiene. Other products included 1,4-hexadiene (*trans*:*cis* ratio = 4) in 4.5% yield, *cis*-3-methyl-1,3-pentadiene in 5% yield, and *trans*-3-methyl-1,3-pentadiene in 5% yield based on 52% recovery of I. These compounds accounted for *ca.* 98% of the products in the 64–94° boiling point range.

The isolation of appreciable quantities of 2-methyl-1,4-hexadiene in these experiments suggests that interaction of the catalyst with I can lead to a species which

(4) No evidence was found that 2-methyl-1,3-pentadiene was produced from *trans*-1,4-hexadiene. The combined amount of *cis*-1,4-hexadiene and 2-methyl-1,3-pentadiene in the product mixture from the *trans* isomer was slightly less than the level of *cis*-1,4-hexadiene (3%) present in the starting material. This also eliminated the possibility that appreciable isomerization of *trans*- to *cis*-1,4-hexadiene took place under these conditions.

(5) Standard mixtures of most products described herein were analyzed by vpc to determine the relationship between mole ratio and relative signal intensity. Product ratios of 2-methyl-1,3-pentadiene were based on signal intensity alone.

possesses a C-4 fragment and ethylene bonded to nickel, such as II. Displacement of the ethylene by propylene could lead to a species like III from which 2-methyl-1,4-hexadiene results. The double bond positional isomerization of the 1,4-dienes and the rearrangement of I to 1,4-hexadiene could arise through the two possible modes of addition of a nickel hydride to a terminal double bond.<sup>6</sup> A 2,1 addition of NiH affords products that, on NiH elimination, could give either the 1,4-diene precursor or its conjugated isomers. However, the 1,2-addition products, possessing terminal C–Ni bonds, could give the 1,4-diene precursor or possibly generate ethylene and a C-4 fragment *via* a Ni–C  $\beta$  elimination.<sup>7</sup> The latter mode of reaction appears, at present, to offer the best rationalization of the formation of a C-7 diene from a C-6 precursor in these experiments. The possible participation of “fragmentation” products such as II or isomeric  $\sigma$ -methylallyl species is being investigated.

Although the rearrangement of I to 1,4-hexadiene can be explained by the intervention of elimination products such as II, other pathways cannot be excluded. The rearrangements of 1-methyl-1-pent-4-enyl derivatives of sodium, lithium, and magnesium<sup>8</sup> provide a close analogy to the gross rearrangement of I. The formation of 2-methyl-1,3-pentadiene from *cis*-1,4-hexadiene can be rationalized by a C–M elimination-addition route analogous to that suggested above. However, the expected diene product here is 2-methyl-

1,4-pentadiene. Our observation that the rate of rearrangement of *cis*-1,4-hexadiene exceeds the rate of double bond isomerization of 2-methyl-1,4-pentadiene and our failure to detect the latter diene in the rearrangement product mixtures indicate that if this process is operating here, the primary 1,4-diene product is isomerized before it becomes free of the metal.<sup>9</sup> Other

(6) We have no evidence that would demonstrate the participation of an actual nickel hydride complex in these reactions. The results described here and elsewhere<sup>1</sup> are consistent with the capability of the catalyst to effect a gross addition of a nickel hydride to an olefinic bond.

(7) An accurate determination of the amount of ethylene present in product mixtures from the reaction of I, propylene, and the catalyst was not achieved. Vpc analyses of the recovered propylene indicated the presence of a component with the retention time of ethylene in amounts *ca.* 20–30 times that present in the propylene reagent. Butadiene was not detected in the reagents or in the product mixtures.

(9) An alternative elimination-addition route involving a propenyl-nickel intermediate could give the conjugated diene directly.

pathways seem equally plausible, particularly one involving the participation of a cyclopropylcarbinyl nickel derivative.<sup>10</sup>

Carbon-metal  $\beta$ -elimination products have been reported in the pyrolyses of neopentyl derivatives of sodium,<sup>11</sup> potassium,<sup>12</sup> and aluminum,<sup>13</sup> systems in which a  $\beta$  elimination of M-H is precluded. The rearrangements of cyclobutylcarbinyl<sup>13b</sup> and cyclopropylcarbinyl<sup>10</sup> Grignard reagents can be pictured as formally involving intramolecular C-M eliminations.

Further study of the 1,4-diene rearrangements and the extension of the investigation to other transition metal systems are in progress.

## Conformational Rigidity<sup>1,2</sup> in Aliphatic Paraffins.

### Synthesis and Determination of Absolute Configuration of (3*S*,5*S*)- and (3*R*,5*S*)-2,2,3,5-Tetramethylheptane

Sir:

The high optical activity in solution of some stereoregular polymers obtained from optically active  $\alpha$  olefins<sup>3</sup> has been attributed<sup>2,4</sup> substantially to the fact that few conformations having high optical rotation of the same sign are allowed for the monomeric unit of such polymers in solution.

As no low molecular weight paraffins were known having  $[M]$  of the same order of magnitude of the one found for the monomeric unit of these polymers, we have synthesized (3*R*,5*S*)- and (3*S*,5*S*)-2,2,3,5-tetramethylheptane (I and II, respectively); for I the existence of two conformations having  $[M] +180$  and  $+60^\circ$ , and for II the existence of one conformation having  $[M] -180^\circ$  can be foreseen by the Brewster method<sup>5</sup> (Chart I).

Chart I

A mixture of the two diastereoisomers I and II has been prepared starting with (−)(*S*)-3-methylpentanal,

(1) A. Abe and M. Goodman, *J. Polymer Sci.*, **A1**, 2193 (1963).

(2) P. Pino, *Advan. Polymer Sci.*, **4**, 443 (1965).

(4) P. Pino, F. Ciardelli, G. P. Lorenzi, and G. Montagnoli, *Makromol. Chem.*, **61**, 207 (1963).

(5) J. H. Brewster, *J. Am. Chem. Soc.*, **81**, 5475 (1959).

bp 120–121° (760 mm),  $n_D^{25}$  1.4002,  $[\alpha]_D^{25} -7$ , 10°, having an optical purity of 97%,<sup>6</sup> and allowing it to react with *t*-butylmagnesium chloride.

The (−)(*S*)-2,2,5-trimethylheptan-3-ol (III) thus obtained, bp 85° (20 mm),  $n_D^{25}$  1.4350,  $d_4^{25}$  0.8305,  $[\alpha]_D^{25} -2.17^\circ$  (neat) (*Anal.* Calcd for  $C_{10}H_{22}O$ : C, 75.88; H, 14.01. Found: C, 75.91; H, 13.80), was oxidized according to Brown<sup>7</sup> to (+)(*S*)-2,2,5-trimethylheptan-3-one (IV), bp 75° (22 mm),  $n_D^{25}$  1.4193,  $d_4^{25}$  0.8183,  $[\alpha]_D^{25} +19.16^\circ$  (neat) (*Anal.* Calcd for  $C_{10}H_{20}O$ : C, 76.86; H, 12.90. Found: C, 76.64; H, 12.96), which was allowed to react with methylmagnesium bromide, yielding (+)(*S*)-2,2,3,5-tetramethylheptan-3-ol (V), bp 90° (20 mm),  $n_D^{25}$  1.4390,  $d_4^{25}$  0.8387,  $[\alpha]_D^{25} +10.13^\circ$  (neat) (*Anal.* Calcd for  $C_{11}H_{24}O$ : C, 76.67; H, 14.04. Found: C, 76.21; H, 14.06).

V was dehydrated by distillation in the presence of  $I_2$  and the mixture of olefins thus obtained was finally hydrogenated at 120° by  $H_2$  in the presence of Raney nickel, yielding a mixture of I and II, bp 61–62° (18 mm),  $n_D^{25}$  1.4202,  $d_4^{25}$  0.7465,  $[\alpha]_D^{25} -0.69^\circ$  (neat),  $[\alpha]_D^{25} -0.83^\circ$  (c 15, *n*-pentane). *Anal.* Calcd for  $C_{11}H_{24}$ : C, 84.52; H, 15.48. Found: C, 84.73; H, 15.59.

The mixture was analyzed by vpc (50-m squalane capillary column); only two components were present, the one with the higher retention time prevailing (60 ± 3%).

By fractional crystallization from propane at −80°, mixtures of I and II having different compositions have been obtained; a sample having a diastereoisomeric purity of 95% showed bp 54–55° (14 mm),  $n_D^{25}$  1.4208,  $[M]_D^{25} -87.47 \pm 0.1^\circ$  (neat),  $[M]_D^{25} -87.52 \pm 1^\circ$  (c 20.47, *n*-pentane). *Anal.* Calcd for  $C_{11}H_{24}$ : C, 84.52; H, 15.48. Found: C, 84.81; H, 15.22.

By plotting the composition of such mixtures vs. their optical rotation and extrapolating at 100% of diastereoisomeric purity, the optical rotation has been calculated for both diastereoisomers.

Taking in account the optical purity of the starting material we have assigned  $[M]_D^{25} +137.8 \pm 3^\circ$  (c 20.47, *n*-pentane)<sup>8</sup> to the lower retention time diastereoisomer,  $[M]_D^{25} -97.5 \pm 4^\circ$  to the higher retention time diastereoisomer.

In order to establish the relationship between the sign of the optical rotatory power and the absolute configuration of the two asymmetric carbon atoms of the diastereoisomers we have prepared a mixture of (3*S*,5*S*)- and (3*S*,5*R*)-2,2,3,5-tetramethylheptane (II and IX, respectively), starting with (−)(*R*)-2,3,3-trimethylbutan-1-ol,  $[\alpha]_D^{25} -15.5^\circ$  (c 3.41, ethanol), optical purity 37.4%.<sup>9</sup> (−)(*R*)-1-chloro-2,3,3-trimethylbutane (VI), bp 89–91° (158 mm),  $n_D^{25}$  1.4313,  $d_4^{25}$  0.8872,  $[\alpha]_D^{25} -19.93^\circ$  (neat) (*Anal.* Calcd for  $C_7H_{15}Cl$ : C, 62.44; H, 11.23; Cl, 26.33. Found: C, 62.39; H, 11.15; Cl, 26.44), was obtained from the alcohol by reaction with  $SOCl_2$  in pyridine, and its Grignard reagent was allowed to react with propanal.

(6) L. Lardicci, F. Navari, and R. Rossi, *Tetrahedron*, **22**, 1991 (1966).

(7) H. C. Brown and C. P. Garg, *J. Am. Chem. Soc.*, **83**, 2952 (1961).

(8) Standard deviation calculated by the least-squares method.

(9) The optical purity has been calculated on the basis of the pure (−)(*R*)-2,3,3-trimethylbutan-1-ol,  $[\alpha]_D^{25} -41.4^\circ$ : M. Farina and E. M. Peronaci, *Chim. Ind.* (Milan), **48**, 602 (1966); *Chem. Abstr.*, **65**, 12091a (1966).

(5*S*)-5,6,6-Trimethylheptan-3-ol thus obtained was not isolated and was oxidized according to Brown<sup>7</sup> to the (–)(*S*)-5,6,6-trimethylheptan-3-one (VII), bp 128–130° (126 mm),  $n_D^{25}$  1.4277,  $\alpha_D^{25}$  –7.00° (neat,  $l = 1$ ) (Anal. Calcd for  $C_{10}H_{20}O$ : C, 76.86; H, 12.90. Found: C, 75.97; H, 12.44), which was purified through its semicarbazone, mp 159–160°.

VII was allowed to react with methylmagnesium bromide, and (–)(*S*)-3,5,6,6-tetramethylheptan-3-ol (VIII), bp 89–92° (18 mm),  $n_D^{25}$  1.4435,  $\alpha_D^{25}$  –7.00° (neat,  $l = 1$ ) (Anal. Calcd for  $C_{11}H_{24}O$ : C, 76.67; H, 14.04. Found: C, 76.28; H, 13.89), was obtained.

VIII was dehydrated by distillation in the presence of  $I_2$ , and the olefins thus obtained were hydrogenated by  $H_2$  at 120° in the presence of Raney nickel, yielding a mixture of (3*S*,5*R*)- and (3*S*,5*S*)-2,2,3,5-tetramethylheptane (IX and II, respectively),  $n_D^{25}$  1.4202,  $[\alpha]_D^{25}$  –26.19° ( $c$  20.58, *n*-pentane). Anal. Calcd for  $C_{11}H_{24}$ : C, 84.52; H, 15.48. Found: C, 84.24; H, 15.43.

Acid-catalyzed rearrangements in the dehydration and acid oxidation steps have to be considered improbable on the basis of published data<sup>10,11</sup> on similar compounds.

As I and II have optical activity of opposite sign, IX must have optical activity of the same sign as II; therefore II must have optical rotation of the same sign as the mixture of II and IX and possess therefore negative optical rotation. Consequently the diastereoisomer I, (3*R*,5*S*), has positive optical rotation.

The mixture of II and IX was analyzed by vpc, as in the case of the mixture of I and II; it contained 55 ± 3% II which has negative optical rotation and higher retention time; taking into account the optical purity of VI, a value of  $[M]_D^{25}$  –108.28 ± 1.30° ( $c$  20.58, *n*-pentane) can be calculated for the molar rotation of the mixture of IX and II. Comparing such a value with the one calculated for the same composition on the basis of the absolute value of the molar rotations of I and II ( $[M]_D^{25}$  115.6 ± 4°), a satisfactory agreement is obtained. This agreement can be taken as an indication that both in the synthesis of the mixtures of I and II and of II and IX no extensive racemization occurs at the two asymmetric centers.

Comparing the values found with the value calculated by the Brewster method,<sup>5</sup> a substantial agreement has been found both concerning the sign and the order of magnitude of the optical rotation of I and II, the discrepancy between the values calculated and found being larger in the case in which a single conformation is allowed (see Table I).

Table I

Compd	Max $[M]_D^{25}$ found ( $c$ 20.47, <i>n</i> -pentane) <sup>a</sup>	$[M]_D$ calcd by Brewster method <sup>a</sup>
I	+137.8 ± 3	+120
II	–97.5 ± 4	–180

<sup>a</sup> In degrees.

Our data confirm the previous hypothesis<sup>4</sup> that, in aliphatic hydrocarbons containing a hydrogen atom

attached to the asymmetric carbon atoms,<sup>12</sup> when the presence of a few conformations having high optical rotation of the same sign can be foreseen by conformational analysis<sup>5</sup> a relatively high optical rotation can be found. This shows the substantial soundness but also the limits of conformational analysis in investigating the conformation of both low and high molecular weight hydrocarbons.

## The Configuration of Vinyl Radicals. The Generation and Trapping of Each Member of a Configurationally Isomeric Pair of Vinyl Radicals

Sir:

We wish to report evidence that vinyl radicals derived from symmetrically disubstituted alkenes exist in a nonlinear configuration capable of facile isomeric interconversion. In addition we are pleased to communicate the results of the first successful attempt to trap the *cis* and *trans* isomers of a vinyl radical prior to their complete equilibration.

Several investigations bearing on the structure of vinyl radicals have been reported recently.<sup>1–7</sup> Under conditions of kinetic control, free-radical additions to terminal acetylenes yield predominantly the product of *trans* addition.<sup>1–3</sup> Skell and Allen<sup>1</sup> attribute this stereoselectivity to the configurational stability of the intermediate vinyl radical. Others<sup>2,3</sup> have suggested that the intermediate radical undergoes rapid *cis*–*trans* equilibration, but that the product-forming abstraction reaction involves stereoselective capture of one isomer of this pair.

Elegant electron spin resonance investigations have shown that at low temperatures in liquid ethylene-ethane<sup>4</sup> or in an argon matrix<sup>5</sup> the unsubstituted vinyl radical possesses a nonlinear configuration which undergoes facile inversion. The minimum activation energy for inversion is estimated to be approximately 2 kcal/mole.<sup>4</sup> The 1-methylvinyl radical generated by irradiation of allene in ethane at –172° is also nonlinear.<sup>4</sup> The inversion rate of the 1-methylvinyl radical is less than that for the unsubstituted vinyl radical. Since inversion of the vinyl radical presumably involves

<sup>a</sup> *cis*- and *trans*-3-chlorohexenes were prepared from isoly pure *trans*- and *cis*-3-hexene, respectively, in the manner by M. C. Hoff, K. W. Greenlee, and C. E. Boord, *J. Am. Soc.*, **73**, 3329 (1951). <sup>b</sup> Reactions were carried out in the previously described.<sup>10</sup> Analysis was by vapor phase chromatography on an 8-ft column packed with a 30% AgNO<sub>3</sub>-se solution coated 20% by weight on Chromosorb P. Relative data were obtained by comparison of peak areas to an internal standard (pentane) of known concentration. datum represents the average of at least three independent runs. In general, yields were reproducible to  $\pm 6\%$  of the reported. Both 3-hexenes were shown to be configurationally stable under the reaction conditions. <sup>c</sup> Bp 119.5°;  $n_D^{20}$  = 1.4341. <sup>d</sup> Bp 114.6°;  $n_D^{20}$  1.4341. <sup>e</sup> THF = tetrahydrofuran; = 1,2-dimethoxyethane.

melting process,<sup>4,6</sup> whereas inversion of the 1-vinyl radical does not,<sup>4</sup> no reliable estimate of relative activation energies for inversion of these species is possible. Thus one cannot employ results of the esr studies to determine whether substitution at the 1 position stabilizes or destabilizes the linear configuration relative to the nonconfiguration for the vinyl radical.

h Fantazier and Kampmeier<sup>6</sup> and Singer and<sup>7</sup> have studied the vinyl radical generating decomposition of *t*-butyl peresters of *cis-trans* pairs of unsaturated acids. Decompositions carried out in hydrogen-donating solvents led to mixtures of olefins; relative concentration was independent of the duration of the perester employed. Although both interpret these results in terms of rapid equilibration of the intermediate vinyl radicals, these data are well explained by postulating the intervention of a single, linear<sup>8</sup> vinyl radical as the intermediate in decomposition of both the *cis* and *trans* peresters.<sup>9</sup> Previous work has shown that the naphthalene radical undergoes an electron-transfer reaction with halides to yield halide ion and alkyl free radicals.<sup>12</sup> In an effort to generate isomeric vinyl free radicals, we have examined the reaction of sodium halenide with *cis*- and *trans*-3-chloro-3-hexene.

For substituted vinyl radicals, the linear (sp) configuration would have at least three inherent advantages relative to the nonlinear form: (1) decreased torsional strain, (2) decreased nonbonded and (3) increased bond strengths resulting from sp hybridization radical site. The imprecision with which the relative stability of linear and nonlinear configurations of the unsubstituted vinyl is known renders impossible an *a priori* estimate of the relative stabilities of the two forms for a substituted vinyl radical. Singer and Kong<sup>7</sup> were able to show that the temperature dependence of the ratio of *cis*- to *trans*-propenylbenzene derived from  $\alpha$ -methylpercinamate could be interpreted logically in terms of rapidly equilibrating nonlinear vinyl radical intermediates. To these results on the basis of a single linear vinyl radical intermediate would require the seemingly unreasonable postulate that the reactivity of hydrogen atom abstraction increases with tempera-

The sole detectable product derived from both chlorohexenes was a mixture of *cis*- and *trans*-3-hexene formed in at least 98% yield. The product analyses for several runs at two temperatures and in two solvent systems are presented in Table I.

In all instances, *trans*-3-hexene predominates in the product mixture, but the ratio of *cis*- to *trans*-3-hexene is decidedly a function of the configuration of the 3-chloro-3-hexene employed. This observation immediately excludes the possible intermediacy of either a single linear (sp) vinyl radical or two isomeric, configurationally stable, nonlinear (sp<sup>2</sup>) vinyl free radicals. Use of sodium naphthalenide as the reducing agent precludes the possibility that a vinyl carbanion is generated directly by a two-electron reduction of 3-chloro-3-hexene.

We conclude that the initial charge-transfer reaction generates a nonlinear vinyl radical which is capable of facile inversion at the radical site, but that the radical is trapped before complete equilibration with its configurational isomer is achieved.<sup>13</sup>

The interconverting vinyl radicals might be trapped either by reduction to a configurationally stable carbanion<sup>14,16</sup> (path a) or by hydrogen abstraction from

(13) Inherent in the interpretation here presented is the assumption that initial electron transfer does not yield a hexenyl chloride radical anion as a discrete intermediate. Several lines of evidence point to the validity of this assumption. Perhaps the most compelling lies in the observation that the reaction cross section for the vapor-phase reaction of sodium atoms with vinyl chloride is on the order of 0.1 to 1.0 Å<sup>2</sup>. If vinyl chloride radical anions were viable species, one would expect this reaction to occur by a "stripping" mechanism. Such a mechanism, however, is known to lead to reaction cross sections on the order of 10<sup>3</sup> to 10<sup>4</sup> Å<sup>2</sup>. Low reaction cross sections are characteristic of the "rebound" mechanism, a path known to be followed in the vapor-phase reaction of alkali metal atoms with molecules, such as methyl iodide, which cannot form radical anions possessing even transient stability. For details, see: D. R. Herschbach, *Advan. Chem. Phys.*, **10**, 319 (1966); K. R. Wilson and D. R. Herschbach, *Nature*, **208**, 183 (1965).

(14) For a summary of the evidence which indicates considerable configurational stability for vinyl carbanions, see D. J. Cram, "Carbanion Chemistry," Academic Press Inc., New York, N. Y., 1965, pp 133-135.

(15) Reduction of both *cis*- and *trans*-3-chloro-3-hexene with sodium in liquid ammonia, a reaction which presumably proceeds via the vinyl carbanion,<sup>16,17</sup> yields alkene with at least 96% retention of configuration. We have yet to establish conclusively that vinyl carbanion isomerization does not occur under the conditions of our investigation. Such isomerization, if it does occur, would not invalidate the present results as evidence for the nonlinearity of the 3-hex-3-enyl radical.

solvent (path b). The fact that *trans*-3-hexene, the thermodynamically more stable isomer,<sup>18</sup> always predominates in the reaction mixture suggests that the former alternative (path a) is adopted. Vinyl free radicals generated by perester decomposition and trapped by reaction with hydrogen atom donors (e.g., cumene) invariably lead to products which, relative to the equilibrium mixture, are markedly enriched in the thermodynamically less stable olefin.<sup>6,7</sup> This is readily explained in terms of increased steric interaction between the donor and acceptor molecules in the transition state for hydrogen atom donation to the *trans* radical as compared with the *cis* radical.<sup>7</sup> The transition state for electron transfer from radical anion to the vinyl radical presumably need not be so highly oriented or so intimate as that for hydrogen atom donation. Thus transfer should take place with equal ease to either the *cis*- or *trans*-vinyl radical.

# The Reaction of Phenyl(trihalomethyl)mercurials with Hexamethylditin. The First Case of Dihalocarbene Insertion into a Metal-Metal Bond to Give a Stable $\text{MCX}_2\text{M}$ System

Sir:

In a recent communication<sup>1</sup> we described the reaction of phenyl(bromodichloromethyl)mercury with bis(trimethylsilyl)mercury and bis(trimethylgermyl)mercury. We proposed that an intermediate formed in these reactions was the product of dichlorocarbene insertion into the Si-Hg and Ge-Hg bonds,  $\text{Me}_3\text{MCCL}_2\text{-HgMMe}_3$  (M = Si and Ge), and that further reactions of this intermediate led to the observed products. This explanation in terms of dihalocarbene insertion into metal-metalloid bonds suggested to us that other such insertions into covalent metal-metal bonds should be possible and that in favorable cases the initial  $\text{M-CX}_2\text{-M}$  systems could be both thermally stable and kinetically stable with respect to further attack by  $\text{CX}_2$  and thus capable of isolation. We have found this to be the case with hexamethylditin in its reaction with phenyl(bromodichloromethyl)mercury and phenyl(dibromochloromethyl)mercury (eq 1).

As an example, we describe the reaction between  $\text{PhHgCCl}_2\text{Br}$  and hexamethylditin. A mixture of 0.10

mole each of the mercurial<sup>2</sup> and hexamethylditin in 250 ml of dry benzene was stirred and heated at reflux under nitrogen for 3.5 hr. The reaction mixture was filtered to remove 30.6 g of gray solid, mp 276–286° (phenylmercuric bromide contaminated with some metallic mercury). Concentration of the orange filtrate at 10 mm resulted in crystallization of 3.64 g of diphenylmercury. Trap-to-trap distillation at 0.8 mm (pot temperature to 100°) removed the remaining solvent and minor amounts of trimethyltin halides; further distillation at  $2 \times 10^{-4}$  mm at room temperature gave small amounts of trimethyltin halides and phenyltrimethyltin,<sup>3</sup> leaving a liquid identified as bis(trimethyltin)dichloromethane,  $(\text{CH}_3)_3\text{SnCCl}_2\text{Sn}(\text{CH}_3)_3$ , bp 48–50° ( $2 \times 10^{-4}$  mm),  $n_D^{25} 1.5326$ , analysis for all elements satisfactory, in 53% yield. Its nmr spectrum ( $\text{CS}_2$ ) showed a sharp singlet at 0.3 ppm downfield from internal tetramethylsilane, with the expected tin satellites ( $J_{\text{Sn}^{119}\text{-H}} = 53.5 \text{ cps}$ ;  $J_{\text{Sn}^{117}\text{-H}} = 51.5 \text{ cps}$ ), and the infrared spectrum (pure liquid) showed bands at 2980 (s), 2915 (s), 1191 (s), 770 (vs), 725 (s), 667 (m), 632 (s), 527 (s), and 507 (sh)  $\text{cm}^{-1}$ . The mass spectroscopically determined molecular weight was 410 (calculated 410); the major fragment was  $\text{Me}_3\text{Sn}^+$ .

A similar reaction using phenyl(dibromochloromethyl)mercury gave bis(trimethyltin)bromochloromethane,  $(\text{CH}_3)_3\text{SnCBrClSn}(\text{CH}_3)_3$ , bp 61° ( $2 \times 10^{-4}$  mm),  $n_D^{25} 1.5502$ , in 39% yield. A satisfactory analysis and mass spectroscopic molecular weight were obtained. The trimethyltin resonance occurred at 0.3 ppm, and the infrared spectrum showed absorption at 2970 (m), 2900 (m), 1190 (m), 768 (vs), 720 (s), 674 (sh), 659 (s), 580 (s), and 526 (vs)  $\text{cm}^{-1}$ . It is of interest to note that the reaction of phenyl(bromodichloromethyl)mercury with hexamethylditin in benzene for 6 days at room temperature gave bis(trimethyltin)dichloromethane in 52% yield.

Attempts to utilize these bis(trimethyltin)dihalomethanes as sources of the carbene  $(\text{CH}_3)_3\text{SnCCl}_2$  have thus far been unsuccessful, mostly because of the thermal stability of these compounds. Bis(trimethyltin)dichloromethane was not decomposed on being heated in a sealed tube at 145° for 40 hr. Attempted reaction with tetramethylethylene at 180° for 4 days gave trimethyltin chloride as the only identifiable organotin product. Similarly, bis(trimethyltin)bromochloromethane survived 20 hr of heating at 130° in the presence of tetramethylethylene without decomposition, but at 190–200° (24 hr) both trimethyltin bromide and chloride were formed.

We have found that nucleophilic attack by iodide ion at the metal in a trihalomethylmercury or -tin compound provides another procedure for the release of  $\text{CX}_2$  from such reagents.<sup>4</sup> In the case of bis(trimethyl-

(2) D. Seyferth and J. M. Burlitch, *ibid.*, 4, 127 (1965).

(3) By-product formation can be rationalized in terms of a reaction between phenylmercuric bromide and hexamethylditin to give trimethyltin bromide and  $\text{PhHgSnMe}_3$ . Decomposition of the latter then gives  $\text{PhSnMe}_3$  and metallic mercury in one mode, diphenylmercury, metallic mercury, and hexamethylditin in another. This point is being examined.

(4) Note analogous release of  $\text{CCl}_2$  from  $\text{Me}_3\text{SnCCl}_2$  and  $\text{Me}_3\text{SnCCl}_2\text{Br}$  in this connection: D. Seyferth, F. M. Ambrecht, Jr., B. Prokai, and R. J. Cross, *J. Organometal. Chem.* (Amsterdam), 6, 573 (1966).

monochloromethane, however, attack of iodide at carbon (eq 2). The product, obtained in

yield, was unstable in air, turning bright orange on exposed surfaces. Its combustion analysis, spectroscopic molecular weight, and infrared spectrum were in agreement with the structure shown.

We recognize that our discovery of the first case of carbene insertion into a metal-metal bond to give the  $-\text{M}-\text{CX}_2-\text{M}-$  system opens up a broad new field of research in the organometallic aspects of carbene chemistry. The study of compounds containing metal-metal bonds has received much attention in the past few years, as the many papers on this subject show.<sup>6</sup> We currently are investigating reactions of phenyl(trihalomethyl)mercurials with compounds containing main group metal-main group bonds, main group metal-transition metal bonds, transition metal-transition metal bonds with the view of preparing and studying new  $\text{M}-\text{CX}_2-\text{M}$  systems.

## Presence of Dehydroalanine in the Antibiotic Nisin and Its Relationship to Activity

When the peptide antibiotic nisin<sup>1,2</sup> was treated with hydrogen bromide<sup>3</sup> (0.1 *N* HCl, 37°, 24 hr) in order to cleave the methionyl peptide bonds, a product of low molecular weight (fractions 91-110; 22 ml) was isolated by gel chromatography on a Sephadex G-25 column (6 × 120 cm; 0.2 *N* CH<sub>3</sub>COOH).

The same product was isolated from control experiments in the absence of the reagent, indicating a bond which is labile under mildly acidic conditions. Aliquots of the pooled and lyophilized fractions from both experiments were analyzed directly using the accelerated method<sup>4</sup> of an amino acid analyzer.<sup>5</sup> A single substance was isolated from the 0.9 × 60 cm column at an effluent volume of 172-182 ml. Lysine was the only amino

acid found in the total hydrolysate. The hydrolysate of the dinitrophenylated product contained only *N*-(dinitrophenyl)lysine, thus indicating the presence of an *N*-(dinitrophenyl) derivative of lysine.

The product of the reaction of this lysine derivative with ninhydrin showed optical densities at 570 and 440 mμ which were reminiscent of those of free lysine. We therefore concluded that the *N*-(dinitrophenyl) substituent is labile under the conditions of the ninhydrin reaction.

Similar observations had been made earlier with pyruvylamino acids formed during cleavage of the aminoacyl bond of *N*-aminoacyl-S-alkylcysteine peptides.<sup>6</sup>

The isolated product was treated with *o*-phenylenediamine.<sup>7</sup> Lysine was liberated in a yield of 50% after 4 hr of reaction at 37°. The fragment thus appeared to be pyruvyllysine. Since dehydroalanine peptides are cleaved with the formation of pyruvyl peptides it is implied that the COOH-terminal sequence of nisin is *dehydroalanyl*lysine. The release of pyruvyllysine in dilute acid is, however, slow (2%/24 hr; cf. below, conditions for the quantitative cleavage).

The molecular weight of nisin was determined by the method of partial substitution.<sup>9</sup> Monodinitrophenyl-nisin was isolated and purified<sup>10</sup> by countercurrent distribution in the system butan-1-ol-acetic acid-water, 4:3:1.

A molecular weight value of 3510 was calculated for this derivative, which is one-half that reported earlier.<sup>2</sup> It is, however, in agreement with the minimum molecular weight determined from the amino acid analyses of nisin (micromoles/0.5 mg; 92% recovery without dry weight correction) and monodinitrophenyl-nisin (micromoles/0.5 mg; quantitative recovery after desiccation): lysine (0.382; 0.267), histidine (0.255; 0.265), ammonia (0.425; 0.459), aspartic acid (0.139; 0.144), serine (0.119; 0.113), lanthionine + β-methylanthionine (0.740; 0.760), proline (0.130; 0.129), glycine (0.400; 0.421), alanine (0.260; 0.270), valine (0.134; 0.138), methionine (0.253; 0.261), isoleucine (0.376; 0.393), leucine (0.257; 0.268); mol wt (nisin), 3290; mol wt (mono-DNP-nisin), 3460.

These data indicate clearly that only one residue of lysine has been dinitrophenylated. Dinitrophenylation did not take place at the COOH-terminal lysine, since pyruvyllysine is still released from mono-DNP-nisin.

The above partial structure of the antibiotic is supported by: (a) the addition of mercaptoacetamide to the double bond of dehydroalanine at pH 4.5 and room temperature (with 1.6 mM nisin solution, the following values were determined for carboxymethylcysteine in the addition product: 0.24 residue, 24 hr, 1.6 mM mercaptan; 1.2 residues, 24 hr, 28 mM mercaptan; 1.2 residues, 72 hr, 56 mM mercaptan; the test for free sulphydryl groups with maleimide was negative and the hydrolysate was free of cystine); (b) a comparison

from Apin & Barrett Ltd., Yeovil, England. The purification of nisin by gel chromatography and countercurrent distribution was published separately by E. Gross, J. L. Morell, and P. Q. Lee.

of the isolated nisin fragment with an authentic sample of pyruvyllysine which was synthesized according to the procedure of Bergmann and Grafe.<sup>11</sup> Pyruvic acid and acetamide were combined to give  $\alpha,\alpha$ -diacetaminopropionic acid which was converted to the azlactone by treatment with acetic anhydride on a steam bath and coupled with N<sup>+</sup>-carbobenzoxyllysine benzyl ester. The protecting groups were removed by catalytic hydrogenation.  $\alpha,\alpha$ -Diacetaminopropionyllysine, mp 145° (uncor). (Anal. Calcd for  $C_{13}H_{24}O_5N_4 \cdot H_2O$ : C, 46.49; H, 7.84; N, 16.76. Found: C, 47.15; H, 7.96; N, 16.59), was treated with HCl in glacial acetic acid (110°, 10 min) to form pyruvyllysine. The synthetic product was eluted from the 60-cm column of the amino acid analyzer<sup>4,5</sup> at the same position as the nisin fragment. The conversion of  $\alpha,\alpha$ -diacetaminopropionyllysine to pyruvyllysine is quantitative, as judged by the disappearance of the peak of  $\alpha,\alpha$ -diacetaminopropionyllysine (effluent volume: 111–123 ml) and the appearance of only the peak corresponding to pyruvyllysine. Free lysine was absent. The ratio of the calibration value of lysine to that of pyruvyllysine is 1.56. Treatment of 1  $\mu$ mole of nisin with HCl in glacial acetic acid (110°, 10 min) released 0.9  $\mu$ mole of pyruvyllysine.

The antibiotic activity of nisin and its derivatives was tested against *Staphylococcus aureus* (ATCC-10537). Nisin strongly inhibits the growth of the bacterium. Monodinitrophenyl nisin was also a growth inhibitor.

The addition product of nisin and mercaptoacetamide showed a very weak growth inhibitory effect, which is perhaps due to partial reactivation of the originally inactive carboxamidomethylthiol nisin. Enzyme systems capable of catalyzing this type of elimination have been described.<sup>12</sup>

The reaction products of the acid-catalyzed cleavage of the C<sup>α</sup>–N bond of dehydroalanine in nisin, namely des-(dehydroalanyllysine)-nisin and pyruvyllysine, are both inactive against *Staphylococcus aureus*. However, when pyruvyllysine was combined with des-(dehydroalanyllysine)-nisin in a ratio of 2:3 and kept in a moist state for 48 hr at room temperature, a recombination product was obtained which again displayed antibiotic activity against *Staphylococcus aureus*. A quantitative determination showed a decrease of 70% in the original amount of pyruvyllysine. This reaction may represent a step in the biosynthesis of the antibiotic. It will undoubtedly be of importance in the contemplated synthesis of biologically active analogs of nisin.

It has thus been clearly shown for the first time that dehydroalanine is present in a naturally occurring peptide antibiotic. The biological activity of nisin is directly related to the presence of dehydroalanine in the molecule. We believe that the addition of mercaptans is the *in vitro* model reaction for the biological action of nisin. Metabolically important compounds, such as sulfhydryl-containing enzymes, glutathione, or coenzyme A, may be intercepted by nisin.

This supposition is being tested, as far as coenzyme A is concerned, on malarial parasites. These are known to be sensitive to deficiency in coenzyme A, whether

this is caused by dietary host deprivation<sup>13</sup> or the presence of antipantothenes.<sup>14</sup>

Two groups of five mice each received four consecutive daily doses of (a) 500 mg/kg of nisin orally; (b) 250 mg/kg of nisin intraperitoneally. On day 4, parasite growth in the mice of group b was reduced by 98% of that on control animals. On day 7, the reduction in parasite growth was 80% for group a.

It remains to be seen whether these effects can be reversed by infusion of acetyl coenzyme A.

**Acknowledgment.** We gratefully record that the support of Dr. B. Witkop has decisively furthered this work. It is a pleasure to acknowledge the skillful assistance of Miss Patricia Q. Lee. We also wish to express our thanks to Dr. R. Schmitt for the bacterial activity tests and to Dr. G. M. Jeffery and his associates, who tested the antimalarial properties of nisin.

## The Tricyclo[2.1.0.0<sup>2,5</sup>]pentane System

Sir:

Recently it was reported that the photolysis of diazo-ketones **1a** and **b** in tetrahydrofuran provided ketones **2a** and **b**, respectively, and the tricyclo[2.1.0.0<sup>2,5</sup>]pentane skeleton was assigned to these compounds mainly on the basis of spectral evidence.<sup>1–3</sup> Doering and Pomerantz, interpreting the spectral data of **2a** in a different manner, suggested an alternative structure (**3**).<sup>4</sup> Although the evidence then available to us and subsequent works<sup>5</sup> have convinced us that the tricyclic structure is the correct representation of **2a** and **b**, we have undertaken an X-ray crystal analysis of a derivative of **2a**. The result now confirms the correctness of our structure and, further, provides the precise geometry of the ring system, which is essential for understanding its unusual properties.

(1) S. Masamune, *J. Am. Chem. Soc.*, **86**, 735 (1964).

(2) Our original nomenclature is corrected: J. D. Connolly and K. H. Overton, *Ann. Rept. Progr. Chem.* (Chem. Soc. London), **348** (1964); J. Meinwald and J. K. Crandall, *J. Am. Chem. Soc.*, **88**, 1292 (1966).

(3) Irradiation of a methanolic solution of **1** gave in addition to **2** (10–15%) the methyl ester of the homologated acid (20%) and a dimeric compound (20–30%), mp 236–237°, for which structure **i** accommodates all experimental data: H. H. Stechl, *Ber.*, **97**, 2681

(1964); N. Obata and I. Moritani, *Bull. Chem. Soc. Japan*, **39**, 2250 (1966). Somewhat to our surprise, a highly purified sample of **1** evolved nitrogen very slowly upon irradiation and provided no ketone **2**. Addition of a sensitizer reproduced the products mentioned above. Copper-catalyzed reaction of **1** in refluxing benzene afforded a trace amount of **2** (at most 1%) (see ref 4).

(12) M. Flavin and C. Slaughter, *Biochemistry*, **3**, 885 (1964).

Crystals of 1,5-diphenyltricyclo[2.1.0.0<sup>2,5</sup>]pent-3-yl *p*-bromobenzoate, mp 138.5–139°, are triclinic:  $a = 5.92$ ,  $b = 8.98$ ,  $c = 17.85$  Å,  $\alpha = 89^\circ 17'$ ,  $\beta = 82^\circ 46'$ ,  $\gamma = 89^\circ 50'$ ,  $Z = 2$ , space group  $P\bar{1}$ . The structure was determined with visual Cu K $\alpha$  data from three-dimensional Patterson and electron-density distributions and refined by ten cycles of block-diagonal least-squares, the final  $R$  value being 0.16 for 1228 reflections. Sections of the electron-density distribution, and a corresponding diagram of the ring system, are shown in Figure 1, and the dimensions of the tricyclopentane ring system are given in Table I.

Table I. Bond Distances (Angstroms) and Valency Angles (Degrees) in the Tricyclopentane System\*

C(2)–C(3)	1.50	C(2)–C(3)–C(4)	81.7
C(3)–C(4)	1.54	C(3)–C(4)–C(5)	89.3
C(2)–C(5)	1.53	C(3)–C(4)–C(1)	92.2
C(1)–C(2)	1.54	C(3)–C(2)–C(5)	91.8
C(4)–C(5)	1.53	C(3)–C(2)–C(1)	92.9
C(1)–C(4)	1.52	C(4)–C(5)–C(2)	81.3
Mean	1.53	C(4)–C(1)–C(2)	81.4
		C(5)–C(4)–C(1)	56.3
C(1)–C(5)	1.44	C(5)–C(2)–C(1)	56.1
C(2)···C(4)	1.99	C(4)–C(5)–C(1)	61.4
		C(4)–C(1)–C(5)	62.3
		C(2)–C(5)–C(1)	62.3
		C(2)–C(1)–C(5)	61.6
External angles at C(1) and C(5) = 134.4–142.1 (six angles), mean 137		C(2)–C(3)–O	115.6
		C(4)–C(3)–O	109.5

\* Standard deviations are 0.05 Å and 3°.

The crystal analysis has confirmed the formulation of the compound as a derivative of tricyclo[2.1.0.0<sup>2,5</sup>]pentane. The great strain in the ring system is indicated by the valency angles given in Table I, there being six C–C–C angles of about 60°, three of about 80°, and four of about 90°. The C(2)···C(4) nonbonded distance is only 1.99 Å. The bond distances, however, do not appear to be greatly influenced by the strain. Six of the C–C distances are in the range 1.50–1.54 Å, mean value 1.53 Å (standard deviation of the mean = 0.02 Å), close to the normal single bond length. The bond which is common to the two three-membered rings, C(1)–C(5), measures  $1.44 \pm 0.05$  Å, so that this bond does seem to be shortened slightly, although the difference from the other bonds (0.09 Å = 1.8 $\sigma$ ) cannot be claimed to be definitely statistically significant.

All the dimensions of the substituent groups are normal. The orientations of the two phenyl groups with respect to the tricyclopentane ring system are similar, but not quite identical, and are probably influenced by intermolecular interactions.

The geometry of a derivative of 2 now being known, we understand better the unusual spectral behavior of this strained system. It is interesting to note that mass

Figure 1.

spectra of 2 and the corresponding hydroxy compound exhibited, in addition to their parent peaks, pronounced peaks at  $M - \text{CO}^+$  and  $M - \text{CHO}$ , respectively. The interpretation of these peaks, of course, must await further studies.<sup>6</sup>

#### Photolysis of Dibenzoylstilbene Episulfoxide. Formation of Monothiobenzil<sup>1</sup>

Sir:

Irradiation of dibenzoylstilbene episulfoxide<sup>2</sup> (1) in benzene at 7–11° gives deep blue monothiobenzil<sup>3</sup>

(1) This work was supported in part by Grant GP-5513 of the National Science Foundation.

(2) D. C. Dittmer and G. C. Levy, *J. Org. Chem.*, **30**, 636 (1965). Its stereochemistry is unknown.

(3) No previous characterization of monothiobenzil has been reported, although it has been suggested as a decomposition product of

(2; 55%) and benzil (56%). This photochemical decomposition of dibenzoylstilbene episulfoxide is the first such decomposition of an episulfoxide, a relatively new class of compounds.<sup>4</sup>

Solutions of about 0.3 g of episulfoxide in 500 ml of benzene were irradiated with a water-cooled, internal mercury arc lamp (Hanovia Type L, 450 w) with or without a Pyrex filter. Purified nitrogen was passed through the solution and reaction vessel for at least 30 min before irradiation, and a positive pressure of nitrogen was maintained during the reaction.

Monothiobenzil was obtained as a blue oil after column chromatography on silicic acid which separated it from the benzil. Monothiobenzil forms the same 2,4-dinitrophenylhydrazone, mp 188–190° (lit.<sup>5</sup> mp 189°), and dioxime, mp 238° dec (lit.<sup>6</sup> mp 238° dec) as benzil. Hydrogen sulfide is evolved in the preparation of these derivatives. Ultraviolet and visible spectra in chloroform [ $\lambda$  247, 325, 606 m $\mu$  ( $\epsilon \sim 30$ )] were similar to those of thiobenzophenone in chloroform [ $\lambda$  248, 329, 598 m $\mu$  ( $\epsilon' \sim 167$ )]. Monothiobenzil exhibits in the mass spectrum a molecular ion at  $m/e$  226 and ions at  $m/e$  198, 178, 121, and 105 formed by the loss of CO, SO, C<sub>6</sub>H<sub>5</sub>CO, and C<sub>6</sub>H<sub>5</sub>CS radicals, respectively. The thioketone is a labile compound, and a satisfactory analysis has not been obtained.

The infrared and ultraviolet spectra, melting point and mixture melting point (95°), and 2,4-dinitrophenylhydrazone (mp 185–189°) of the benzil produced in the irradiation are identical with those of authentic benzil.

Monothiobenzil is of interest because of the possibility of interaction between sulfur as an electron acceptor and oxygen as an electron donor as indicated in 3. The interaction of two sulfur atoms on adjacent

carbon atoms in the dianion *cis*-dimercaptomaleonitrile has been considered.<sup>8</sup> No definite evidence for or against interaction between sulfur and oxygen has been obtained, but the mass spectrum of monothiobenzil indicates no ion is formed by loss of sulfur alone, whereas in the mass spectrum of thiobenzophenone an important fragment corresponds to the parent ion minus sulfur.<sup>9</sup>

## A Novel Method for the Reduction of $\alpha,\beta$ -Unsaturated Ketones

Sir:

We wish to report a novel method for the selective reduction of only those double bonds which are conjugated with the carbonyl group as in an  $\alpha,\beta$ -unsaturated ketone under the nonreducing conditions. This method involves the condensation of a ketone with benzylamine to give the corresponding Schiff base (I), which on treatment with a base (0.1–1 mole) such as potassium *t*-butoxide undergoes rearrangement to II (cf. the isomerization of  $\beta,\gamma$ -unsaturated ketones  $\rightarrow$   $\alpha,\beta$ -unsaturated ketone analogs). The rearrangement can be carried out with or without any solvent. Various solvents used are benzene, monoglyme, diglyme, dimethyl sulfoxide, hexamethylphosphoramide, *t*-butyl alcohol, and other protic and aprotic solvents. Hydrolysis of II with dilute acetic acid furnishes the corresponding saturated aldehyde or a ketone with the concomitant formation of benzaldehyde. Rearrangement can also be effected with an acid catalyst such as *p*-toluenesulfonic acid, but the yields are unsatisfactory in this case.

The method may be illustrated by the reduction of a typical  $\alpha,\beta$ -unsaturated ketone such as *d*-carvone (III), as described below.

A mixture of 20 g (0.084 mole) of the benzylamine Schiff base of *d*-carvone (bp 113° (0.02 mm)); *Anal.* Found: C, 85.67; H, 8.60) and 0.93 g (0.0084 mole) of potassium *t*-butoxide in 75 ml of anhydrous diglyme was stirred at room temperature and under nitrogen for 20 min. To the resulting solution 30 ml of 50% acetic acid was added and stirring was continued for another 20 min. After the usual work-up, the product, dihydrocarvone, bp 90–92° (15 mm) (oxime mp 88°; lit.<sup>1</sup> mp 88–89°) was obtained in 75% yield.

Other monocyclic ketones reduced by this method are 3-methyl- $\Delta^2$ -cyclohexenone, 3,5-dimethyl- $\Delta^2$ -cyclohexenone, 3,4-dimethyl- $\Delta^2$ -cyclohexenone, 2,4-dimethyl- $\Delta^2$ -cyclohexenone, and isophorone, the overall yields being 40–70%.

The I–II rearrangement was found to be slower for the ketones with alkyl groups at the  $\beta$  position than for those lacking such substitution. For instance, the

(1) J. L. Simonson, "The Terpenes," Vol. I, 2nd ed, The University Press, Cambridge, England, 1953, p 352.

room temperature rearrangement of the Schiff base of 3,5-dimethyl- $\Delta^2$ -cyclohexenone with 0.1 mole of potassium *t*-butoxide in hexamethylphosphoramide solution proceeded to the extent of only 56.7% in 1 hr.<sup>2</sup> On the other hand, under similar conditions the rearrangement of the Schiff bases of 2,4-dimethyl- $\Delta^2$ -cyclohexenone and *d*-carvone was complete within 5 min. The slowness is most likely due to (a) the intermediacy of a tertiary carbanion in contrast to the secondary carbanion arising from the Schiff's bases of ketones lacking substitution at the  $\beta$  position, and (b) hyperconjugative and inductive effects of the alkyl groups enhancing the ground-state stability of the Schiff bases of the  $\beta$ -substituted ketones. The rate of the rearrangement could, however, be accelerated by increasing the amount of base and the reaction temperature. For instance, the rearrangement of the Schiff base of 3,5-dimethyl- $\Delta^2$ -cyclohexenone with 1 equiv of KO-*t*-Bu was complete within 40 min at 100°.

Reduction of bicyclic ketones, e.g.,  $\Delta^{1(9)}$ -2-octalone and 10-methyl- $\Delta^{1(9)}$ -2-octalone, when the rearrangement of their Schiff bases was stopped after 30–40% completion, led to the corresponding *trans*-decalones. These results indicate that, in this mode of reduction,

(2) The extent of the rearrangement of the Schiff base was followed by the disappearance of bands due to benzylic protons in the nmr spectrum and by the determination of saturated and unsaturated ketones in the hydrolyzed product by glpc.

the transition state for the kinetic protonation at the  $\beta$ -carbon atom is analogous to that involved in the metal-ammonia reduction of these ketones.<sup>3</sup> It is, however, obvious that under equilibrating conditions the rearrangement of these Schiff bases would lead to a thermodynamic mixture of the *cis* and *trans* isomers and thus provide a direct method for the determination of the thermodynamic stabilities of various substituted  $\Delta^1$ -octalins.<sup>4</sup> Further work along these lines is in progress.

Reduction of steroidal  $\Delta^4$ -3-ketones, e.g., testosterone and cholestenone, proceeded in relatively poor yields in our hands, due to the formation of side products. Pregna- $\Delta^{5,16}$ -dien-3 $\beta$ -ol-20-one was reduced to pregnenolone in 40% yield. Reduction of cholest- $\Delta^{4,6}$ -dien-3-one led to a mixture of cholest- $\Delta^4$ - and  $\Delta^5$ -en-3-ones in 50% yields.<sup>5</sup>

(4) The Schiff base of  $\Delta^{(9)}$ -2-octalone on heating with 0.1 mole of potassium *t*-butoxide at 130° for 19 hr gave a 1:4 mixture of *cis*- and *trans*-decalones.

(5) The formation of  $\Delta^4$ -3-one is due to the protonation of IV at C-4 which is analogous to the protonation of  $\Delta^{5,6}$ -enolate. Also see S. K. Malhotra and H. J. Ringold, *J. Am. Chem. Soc.*, **87**, 3228 (1965), and references cited therein.

## Chlorine(III) Oxide, a New Chlorine Oxide

Sir:

There are four known stable oxides of chlorine:  $\text{Cl}_2\text{O}$ ,  $\text{ClO}_2$ ,  $\text{Cl}_2\text{O}_6$  (which dissociates to  $\text{ClO}_2$  in the vapor), and  $\text{Cl}_2\text{O}_7$ . These compounds have been known and characterized for a long time and they are discussed in inorganic textbooks. In the course of a study of the decomposition of chlorine dioxide<sup>1</sup> we have discovered a new oxide of empirical formula  $\text{ClO}_{1.5}$ . We believe this chlorine(III) oxide to be  $\text{Cl}_2\text{O}_3$ , and we wish to report its synthesis and behavior in this communication.

When gaseous  $\text{ClO}_2$  is admitted from a Pyrex storage vessel at room temperature to another Pyrex vessel at a temperature above about 50°, it explodes after an induction period. We found that the induction period

(1) E. T. McHale and G. von Elbe, to be published.

is reduced or even eliminated by exposure of the storage vessel to light, and the effect of such illumination persists for many hours. Obviously, a photochemical reaction occurs which produces a fairly stable compound that acts as a promoter of the explosive decomposition of  $\text{ClO}_2$ . The existence of such promoter has already been noted in an earlier study of the chain mechanism of  $\text{ClO}_2$  decomposition,<sup>2</sup> but the substance has hitherto not been identified.

Several workers have reported the photolysis of  $\text{ClO}_2$ ,<sup>3,4</sup> where the lowest temperature was  $15^\circ$ . The identified products comprise  $\text{Cl}_2$ ,  $\text{O}_2$ , and  $\text{Cl}_2\text{O}_6$ . The last is described<sup>5</sup> as a red liquid at room temperature, which freezes at  $+3.5^\circ$  to an orange solid. The vapor pressure as a function of temperature has been carefully measured from  $-30$  to  $+15^\circ$ , it being 0.31 torr at  $0^\circ$ . In the vapor phase this oxide is almost completely dissociated into  $\text{ClO}_2$ .<sup>6,6</sup> Prolonged irradiation of  $\text{Cl}_2\text{O}_6$  produces the heptoxide,  $\text{Cl}_2\text{O}_7$ .<sup>8</sup> We have prepared both  $\text{Cl}_2\text{O}_6$  and  $\text{Cl}_2\text{O}_7$  by the procedures described in the literature and have tested the effect of these and other compounds on the  $\text{ClO}_2$  induction period. The results were substantially negative for  $\text{Cl}_2\text{O}_7$ ,  $\text{Cl}_2$ , and  $\text{O}_2$ ; this also applies to  $\text{Cl}_2\text{O}$ ,<sup>2</sup> whereas  $\text{Cl}_2\text{O}_6$  (or  $\text{ClO}_3$ ) was found to be an inhibitor rather than a promoter. The promoting agent is thus another, hitherto unknown photolysis product.

We used the following method for isolating this product. One millimole of  $\text{ClO}_2$  (see ref 1 for preparation and purification) was admitted to a 500-cc spherical Pyrex flask. A U-tube manometer was connected directly to the top of the vessel, the mercury being protected with a layer of Kel-F oil. The lower half of the reactor was immersed in a  $-45^\circ$  bath, and ultraviolet light from a 100-w lamp was directed at the upper half. Under these conditions  $\text{ClO}_2$  remains a gas (vapor pressure, 37 torr at  $-45^\circ$ ); no detectable  $\text{Cl}_2\text{O}_7$  is formed, and the condensable products,  $\text{Cl}_2\text{O}_6$  and the unknown agent, collect at the vessel bottom as a dark brown crystalline solid. Within 20–30 min the  $\text{ClO}_2$  is completely consumed. The  $\text{Cl}_2$  and  $\text{O}_2$  products are pumped away and the bulb evacuated to  $<0.1$  torr with no indication of loss of any of the dark brown solid.

At  $-45^\circ$  the solid decomposes very slowly, an estimated 10% in 20 min. At  $-78^\circ$  it is stable indefinitely. When the  $-45^\circ$  bath is replaced with a  $0^\circ$  bath, the pressure rises from zero to some constant value of the order of 15 torr depending on the amount of brown solid originally formed, and no further increase takes place. A solid orange residue remains after the pressure rise which has a vapor pressure of *ca.* 0.3 torr at  $0^\circ$  and a melting point of  $+3^\circ$ , in near-perfect agreement with the data reported for  $\text{Cl}_2\text{O}_6$ . If the warm-up from  $-45$  to  $0^\circ$  is conducted in darkness, one observes a series of flashes of orange light throughout the vessel, indicating that the brown material explodes as it gasifies. The flashes continue until all the brown solid is gone, leaving the orange  $\text{Cl}_2\text{O}_6$  residue plus the gaseous explosion products of the other photolysis product.

The brown solid then is a mixture of  $\text{Cl}_2\text{O}_6$  and the unidentified photolysis product. We have determined the composition of this unknown product by measuring the  $\text{O}_2/\text{Cl}_2$  ratio of the decomposition products. The results of duplicate measurements on three separate preparations were: 1.42, 1.43; 1.59, 1.59; 1.50, 1.48. The average of these measurements is  $1.50 \pm 0.1$ .

The analytical technique consisted of measuring the total pressure of the explosion products,  $\text{O}_2$  and  $\text{Cl}_2$ , in the reactor of  $0^\circ$ , allowing for a vapor pressure of 0.3 torr of  $\text{Cl}_2\text{O}_6$ , and then measuring the  $\text{O}_2$  pressure after  $\text{Cl}_2$  had been condensed on a cold spot at the bottom of the bulb at  $-196^\circ$ . Numerous tests on synthetic mixtures of known  $\text{O}_2/\text{Cl}_2$  ratios confirmed the validity of the technique. The temperature of  $-196^\circ$  ensured that only  $\text{O}_2$  remained in the gas phase, and no  $\text{O}_2$  itself condensed since the vapor pressure is *ca.* 160 torr at  $-196^\circ$ , and in all experiments the  $\text{O}_2$  pressure in the 500-cc reactor after cooling ranged from 6.0 to 8.5 torr. Furthermore, we took care to satisfy ourselves that only  $\text{O}_2$  and  $\text{Cl}_2$  were formed in the explosive decomposition.

Parenthetically it should be noted that this new oxide was probably previously prepared in small quantities by Goodeve and Richardson.<sup>5</sup> They report that the color of  $\text{Cl}_2\text{O}_6$ , prepared photolytically, can be taken as an indication of purity, and that at low temperature an "impurity" colored the hexoxide dark brown.

To summarize, this new chlorine oxide is a dark brown solid at  $-45^\circ$  and below when condensed with  $\text{Cl}_2\text{O}_6$ . It has a vapor pressure  $<0.1$  torr and decomposes slowly at  $-45^\circ$ , but not at all at  $-78^\circ$ . Since its vapor explodes at approximately 1–2 torr pressure and temperatures well below  $0^\circ$ , it does not lend itself to a determination of physical properties such as boiling point, melting point, and vapor pressure. The empirical formula is  $\text{ClO}_{1.5}$ , and we believe it to be the unknown chlorine sesquioxide,  $\text{Cl}_2\text{O}_3$ . This last formula is the most reasonable, but it would be desirable to determine the molecular weight since theoretically the molecular formula could be  $(\text{ClO}_{1.5})_n$  with *n* any even integer. Again, however, such measurements as vapor density or freezing point depression are not feasible with this compound.

The new oxide is very likely formed in the reactions

These are just two of many reactions in the mechanism, since we find  $\text{Cl}_2\text{O}_6$ ,  $\text{O}_2$ , and  $\text{Cl}_2$  as primary products. The actual over-all stoichiometry at  $-45^\circ$  which we have measured by mass balance is

but this equation is probably unique to our reaction conditions.

Assuming that *n* = 2, it is possible to infer the structure of  $\text{Cl}_2\text{O}_3$  from this study and what is known of the other chlorine oxides. The most stable of the chlorine oxides are  $\text{Cl}_2\text{O}^7$  and  $\text{Cl}_2\text{O}_7$ ,<sup>8</sup> which decompose homogeneously and must be heated to  $100^\circ$  or above to decompose at measurable rates. These both contain the

(8) R. V. Figini, E. Colocchia, and H.-J. Schumacher, *Z. Physik. Chem. (Frankfurt)*, 14, 32 (1958).

Cl-O-Cl linkage in their structures.  $\text{ClO}_2$  is much less stable and decomposes heterogeneously at  $40\text{--}50^\circ$ ,<sup>2</sup> while  $\text{Cl}_2\text{O}_6$  is even less stable and decomposes heterogeneously at room temperature.<sup>5</sup> If  $\text{Cl}_2\text{O}_6$  had a stability-imparting Cl-O-Cl linkage, one would expect to find it a considerably less labile molecule than it is.

A consideration of the relative volatilities of the oxides likewise indicates the structure.  $\text{Cl}_2\text{O}_7$  is a relatively volatile material with a vapor pressure of 80 torr at  $0^\circ$ ,<sup>9</sup> and an estimated 1 torr at  $-45^\circ$ .  $\text{Cl}_2\text{O}_6$  is an oil at  $20^\circ$ , with a vapor pressure of approximately 1 torr, and 0.31 torr at  $0^\circ$ .<sup>5</sup> Since  $\text{Cl}_2\text{O}_6$  is less volatile than  $\text{Cl}_2\text{O}_7$ , its structure can hardly be of the same type as  $\text{Cl}_2\text{O}_7$ , whereas a structure similar to  $\text{Cl}_2\text{O}_6$  accounts for its behavior very satisfactorily.  $\text{Cl}_2\text{O}_6$  is bound in the condensed phase by a Cl-Cl bond which is only 1.7 kcal;<sup>10</sup> it exists almost entirely as  $\text{ClO}_2$  in the vapor phase.<sup>5,6</sup> Accordingly, we believe the structure of  $\text{Cl}_2\text{O}_6$  to be

with a weak Cl-Cl bond of a few kilocalories. The extreme instability is then due to dissociation to yield the reactive  $\text{ClO}$  radical. The heat of formation of  $\text{Cl}_2\text{O}_6$  should then be of the order of  $+45$  kcal/mole, since the heats of formation of  $\text{ClO}$  and  $\text{ClO}_2$  are  $+24$  and  $+25$  kcal/mole, respectively.<sup>11</sup>

## 2,3-Iminosqualene, a Potent Inhibitor of the Enzymic Cyclization of 2,3-Oxidosqualene to Sterols

Sir:

Recent studies have demonstrated that the squalene analog 10,11-dihydrosqualene is not readily cyclized under the influence of the sterol-producing enzymes of rat liver homogenate, but instead is converted to a mixture of mono- and dioxido derivatives by addition of oxygen to either or both of the terminal olefinic groupings,<sup>1</sup> a fact which suggested that 2,3-oxidosqualene (**1a**) might be an intermediate in the biosynthesis of sterols from squalene. This possibility has been fully verified by an appropriate series of experiments.<sup>2,3</sup> More recently, the enzyme which effects anaerobically the conversion of 2,3-oxidosqualene has

been separated from hog liver microsomes in water-soluble form and has been partially purified.<sup>4</sup> This note describes the results of an investigation aimed at the development of an effective inhibitor for this enzyme, 2,3-oxidosqualene cyclase.

Experiments to determine inhibition were performed anaerobically with solutions of partially purified 2,3-oxidosqualene cyclase in amounts sufficient to effect *ca.* 30% conversion of  $25\ \mu\text{M}$   $^{14}\text{C}$ -labeled 2,3-oxidosqualene to lanosterol in 30 min. Parallel, duplicate runs were made with and without the substance under test. Table I records some of the data which have been obtained from the study of ( $\pm$ )-2,3-iminosqualene (**1b**), ( $\pm$ )-2,3-sulfidosqualene (**1c**), and decahydro-( $\pm$ )-2,3-iminosqualene as potential inhibitors. The results summarized in the table show strikingly that 2,3-iminosqualene (**1b**) is a powerful inhibitor of 2,3-

- 1a, X=O  
b, X=NH  
c, X=S

oxidosqualene cyclase, as might be expected from the greater basicity of **1b** as compared with **1a** and the supposition that the enzyme operates on the oxygen of **1a** as a proton-transfer reagent. Decahydro-**1b**, although a weaker inhibitor than **1b**, is still effective; evidently the high basicity of the imino grouping largely offsets the geometric perturbations in the enzyme-inhibitor complex due to the saturated carbon chain. Relative to these aziranes, 2,3-sulfidosqualene (**1c**) is a weak inhibitor. It is also inert to 2,3-oxidosqualene cyclase, as could be shown by experiments with  $^{14}\text{C}$ -labeled **1c** in which essentially all the radioactivity was accounted for in the recovered substrate **1c** after incubation with the cyclizing enzyme. Little, if any, inhibition of lanosterol synthesis from the oxide **1a** and 2,3-oxidosqualene cyclase was observed with 3 $\beta$ -amino-

lanosta-8,25-diene, 3 $\beta$ -aminolanost-8-ene, or squalene at concentrations approximating those of substrate 1a.

The inhibitory effect of 2,3-iminosqualene on the enzymic conversion of 1a to lanosterol has been utilized to permit the accumulation of 2,3-oxidosqualene using squalene as substrate with rat liver homogenate.<sup>2</sup> Equilibration of 0.12  $\mu$ mole of ( $\pm$ )-2,3-iminosqualene with 2 ml of rat liver homogenate for 5 min at 37° followed by addition of <sup>14</sup>C-labeled squalene (0.075  $\mu$ mole) and ca. 5 mg of reduced triphosphopyridine nucleotide and aerobic incubation for 3 hr led after chromatographic isolation to 2,3-oxidosqualene in 25–30% yield.<sup>5</sup> The isolated labeled oxide 1a was further identified by its transformation to labeled lanosterol by anaerobic incubation with 2,3-oxidosqualene cyclase for 1 hr (80% conversion).

The synthesis of ( $\pm$ )-2,3-iminosqualene was accomplished by the sequence: all-*trans*-( $\pm$ )-2,3-oxidosqualene (1a)<sup>2</sup>  $\rightarrow$  2-azido-3-hydroxysqualene (HN<sub>3</sub>)  $\rightarrow$  2-azido-3-*p*-toluenesulfonylsqualene (*p*-toluenesulfonyl chloride-pyridine)  $\rightarrow$  ( $\pm$ )-2,3-iminosqualene (1b) (LiAlH<sub>4</sub>).<sup>6</sup> The structure of 1b was confirmed chemically by its conversion using N-nitroso-4-nitrocarbazole to squalene and nitrous oxide.<sup>7</sup> Decahydro-2,3-iminosqualene was synthesized by hydrogenation of 1b with palladium-on-charcoal catalyst in ethanol; the mass spectrum showed a peak due to the molecular ion at *m/e* 435, as expected for a decahydro derivative of 1b, and no peak at *m/e* 425, indicating the absence of unreduced 1b. ( $\pm$ )-2,3-Sulfidosqualene was obtained from the reaction of ( $\pm$ )-1a with potassium thiocyanate in ethanol;<sup>8</sup> independent chemical evidence for the formulation of this product as 1c was obtained from the reaction with *n*-butyllithium which produced squalene cleanly.<sup>9,10</sup>

Work on various aspects of the enzymic cyclization of 2,3-oxidosqualene and its analogs is continuing.

**Acknowledgments.** We are indebted to Professor Konrad Bloch for numerous helpful discussions during the course of this investigation. Financial support from the National Science Foundation (Grant GP-221) and the National Institutes of Health (Grant HE-02477; Predoctoral Fellowships to P. O. de M. 1965–1967) is also gratefully acknowledged.

(5) 2,3,22,23-Dioxidosqualene was also isolated in 3–10% yield. The absence of sterol formation in this experiment was indicated by the lack of radioactivity in the sterol fraction obtained after precipitation with digitonin.

(6) New substances were characterized by infrared, nuclear magnetic resonance, and mass spectroscopy. Homogeneity was indicated by thin-layer chromatographic techniques.

## Synthesis of a Medium Ring Containing Bridge Biphenyl by Photochemically Induced Intramolecular Arylation

Sir:

Recent interest in intramolecular radical cyclization reactions,<sup>1</sup> particularly those involving aryl radicals,<sup>2</sup> prompts us to present details of a photochemical route to a bridged biphenyl containing a medium ring.

Photolysis of aryl iodides in benzene provides a useful method for the synthesis of substituted biphenyls.<sup>3</sup> An extension of this reaction has been employed for effecting intramolecular arylations leading to phenanthrenes,<sup>4</sup> and more recently to the synthesis of aporphines.<sup>5</sup>

The results presented in this communication demonstrate that photochemically induced intramolecular arylation may be employed not only in the formation of six-membered rings but also for constructing seven- and eight-membered cycles.

Irradiation<sup>6</sup> of a dilute aqueous solution of the iodoaromatic compound I, as the hydrochloride, gave after 200 hr the photocyclized product, 6,7-dihydro-5H-dibenz[*c,e*]azepine (2),<sup>7</sup> mp 74–76°, in 57% yield, together with 13% of starting material. Similarly, irradiation of N-( $\beta$ -phenethyl)-2-iodobenzylamine (3) as the hydrochloride in water for 113 hr, under the same conditions as described above, afforded the photocyclized product 4 (R = H) in 25% yield, mp 119–120°<sup>8</sup> [hydrochloride mp 321–322° dec],  $\lambda_{\max}$  276

*m* $\mu$  (log  $\epsilon$  2.89),  $\lambda_{\text{ab}}$  231 *m* $\mu$  (log  $\epsilon$  4.15), pmr: eight-proton multiplet,  $\delta$  7.38–6.95 (aromatic hydrogens), one-proton broad doublets, 3.83 ( $J$  = 15 Hz), 3.10 ( $J$  = 15 Hz) (C<sub>6</sub>H<sub>5</sub>CH<sub>2</sub>N),<sup>9</sup> five-proton multiplet, 3.20–2.10 (–HNCH<sub>2</sub>CH<sub>2</sub>), mol wt (mass spectrum), 209, together with N-( $\beta$ -phenethyl)benzylamine (10%). The

# Book Reviews

**The Molecular Orbital Theory of Conjugated Systems.** By LIONEL SALEM, Maître de Recherche in the French National Research Center (C.N.R.S.), Laboratoire de Chimie Physique, Faculté des Sciences, Orsay. W. A. Benjamin, Inc., 1 Park Ave., New York, N. Y. 1966. xvi + 576 pp. 16 × 23 cm. \$19.75.

The molecular orbital theory of large organic molecules has represented a curious gap in scientific publishing; the available books in this area have been of an elementary nature, intended to introduce chemists to the simple Hückel (HMO) treatment and consequently paying little attention to more sophisticated recent developments. Dr. Salem's book represents an attempt to fill a major part of this gap, by covering the application of MO theory to the  $\pi$  electrons of conjugated molecules.

Successive chapters in the book discuss the HMO method and its application to various systems; the SCF MO method and various pseudo-self-consistent treatments such as the Wheland-Mann method; ground-state properties of molecules including bond lengths, resonance energies, charge distributions, dipole moments, etc.; the magnetic properties of closed-shell molecules and nmr spectroscopy, including the theory of ring currents, chemical shifts, and coupling constants; esr; chemical reactivity; light absorption; and the theory of molecular distortions, including bond alternation and the Jahn-Teller effect.

The trouble with this book is that it seems to have been written at least ten years ago, and recently updated by a hasty inclusion of references to recent work. Far too much emphasis is laid on early investigations based on the HMO method; for example, in the chapter on light absorption, 84 pages are devoted to work published before 1956 and using the simple HMO method or variants of it, while the coverage of recent developments is wholly inadequate. Ruedenberg's work is not even mentioned. The chapter on reactivity could have been written in 1954, while the section on esr spectroscopy omits all reference to recent open-shell calculations, using annihilation operator techniques. Much of the material in the first and third chapters also seems out of place, dealing in great detail with problems that were highly topical in the early fifties.

The introductions to SCF MO theory in Chapter 2, and to the theory of magnetic effects in Chapter 4, are very inadequate; hardly anyone who was already unfamiliar with this material would have the background to understand them. One gets the impression from odd phrases throughout the book that the author regards SCF MO theory as far too complicated and difficult for general use and therefore not worth discussing in detail; thus no indications are given of its use in practice or the choice of parameters in it. This attitude would again be understandable if the book was originally written ten years ago and inadequately revised. Again, the author

seems to suggest that computers are rare and exotic devices, to be used only in cases of extreme emergency (p 428: "A drawback however (i.e., in SCF MO theory) is the labor involved in calculating self-consistent field orbitals;" p 432: "The numerical expressions derived from (7.103) become quite complicated and the calculations tedious. One solution is to use a computer.").

In spite of these shortcomings, this is a useful book. It contains a great deal of information and is a good source of references to the literature. If the price were more reasonable, it could be generally recommended, if only as a stop-gap until something better appears.

**Solid State Chemistry, Whence, Where and Whither.** By J. ARVID HEDVALL, D.Ph., D.Ph.(H.C.), D.Eng.(H.C.), D.Tech.(H.C.), Emeritus Professor at the Chalmers University of Technology, Gothenburg, Sweden. American Elsevier Publishing Co., Inc., 52 Vanderbilt Ave., New York, N. Y. 1966. v + 100 pp. 14 × 21.5 cm. \$6.50.

This is a very short book (87 pages of text) which is intended as a brief survey of the development of solid-state chemistry from the first experiments more than 50 years ago to the present. Heavy emphasis is placed upon the author's own work and interests. The presentation is frequently in narrative form and deals primarily with the qualitative exploratory period of work with heterogeneous solid-state reactions.

There are 14 chapters in which are presented discussions of such diverse topics as exchange reactions, corrosion, absorption, photoactivity, catalysis, and changes in magnetic state. The author presents, in a very abbreviated and qualitative form, the factors which affect the reactivity of solids and indicates routes for further research and industrial development. Little or no mention is made of the extensive contributions made to our understanding of solids from the vast amount of research done with metals and semiconductors in recent years.

This book may be of interest to those who would like to gain the flavor of the historic development of several areas of solid-state chemistry. In this reviewer's opinion, the book is somewhat overpriced at \$6.50.

## NOW . . . A SHORTER EDITION FOR THE EXIGUOUS STUDENT

It will now cost some four dollars (\$4.00) less to use the best text available for the introductory organic chemistry course. The short edition of Roberts and Caserio will be available on April 1; this alternate version of **Basic Principles of Organic Chemistry** has been reduced from 1400 to 840 pages with the organization and content of the original edition left largely intact. Much of the more advanced material has been deleted, and the difficult problems removed.

As a matter of interest, many schools now plan to use the short edition (MODERN ORGANIC CHEMISTRY) for regular students, and the original text for chemistry majors. Incidentally, there will be many new problems of the drill variety added to the revised Student Supplement.

## For the chemistry of positive ions.

This new general-purpose mass analyzer makes Varian's Syrotron™ Ion Cyclotron Resonance Mass Spectrometer an even more powerful tool for studying the chemistry of positive ions. Research indicates that information obtained on positive ions in the gas phase is applicable to the liquid phase.

In the study of positive ion chemistry in the gas phase, the Syrotron can identify all possible reactants leading to all possible products, and obtain a measure of reaction rates. The unique capability for double-resonance experimental procedures lets you establish unequivocally the ions involved in given ion-molecule reactions. *No other instrument, commercially available, can give you this capability.*

With its plug-in feature, the standard general-purpose mass analyzer can easily be replaced with units optimized for special studies, such as optical irradiation of the sample, or negative ion studies. And with the overall flexibility of the Syrotron, which lets you easily modify the vacuum system or vary sample introduction, you can also perform studies in photo ionization, appearance potentials, unimolecular decomposition, as well as fundamental mass spectrometry.

When you need to study how ions react, how they react, how they change, or how they formed... the Syrotron is your best answer. additional information, contact your local Varian representative or write us.

## Programming Complex Problems Simply

1. A program for GRAPHIC I lets engineer W. H. Ninke draw a circuit diagram on a cathode ray tube, using familiar component symbols.

2. In describing a circuit problem to the computer, he guides nodes (circuit junction points) into place with a light pen.

3. He next guides components into place. Where necessary, he can mark certain ones "variable" by placing a slant arrow across each

4. With a keyboard, which resembles a typewriter, he inserts the values of the various components and the operating conditions of the circuit.

5. He asks the central computer to use this information to calculate and display a curve of gain vs frequency response for the circuit.

6. Seeing the curve, he may modify the circuit, insert new values for variable components, request the computer to recalculate performance

Scientists at Bell Telephone Laboratories have improved communications between engineers studying circuits and the computer that helps them. The key is an experimental console on which the engineer works with familiar graphics: component symbols, performance curves, and so on.

The engineer composes a circuit on a cathode-ray tube, inserts component values, makes certain components variable, as required. The display equipment responds immediately to his commands. As he proceeds, the console displays appropriate operating instructions. At his request, the computer calculates and displays circuit performance. He may adjust the variable components or revise the circuit and call for performance calculation again.

This sophisticated tool is not needed in routine circuit design. Its principal use will be where well established, highly automated design procedures do not exist—for example, when investigating effects of temperature, component tolerances, and stray coupling. The "conversational" ability promises to make this hardware-software system a valuable laboratory tool.

The console itself is GRAPHIC I, a man/machine computer terminal developed at Bell Laboratories. It includes a cathode-ray display, a keyboard for inserting letters or numbers, a light pen for selecting and positioning symbols on the tube, and a small display-control computer. Network analysis is handled by a separate large digital computer on a shared-time basis.

The circuit-analysis program is only one of several compiled for GRAPHIC I at Bell Laboratories. Others help generate integrated-circuit masks, design wiring patterns for magnetic-core logic devices, or retrieve documents. A special compiler (program for making programs) has been developed for GRAPHIC I. It is GRIN—for GRAPHIC INput.

Based on GRAPHIC I, a new generation of graphic terminals will be installed as part of an overall computer facility at Bell Laboratories.

# WERNER CENTENNIAL

## ADVANCES IN CHEMISTRY SERIES NO. 62

Forty-two papers survey the work of Alfred Werner, founder and systematizer of coordination chemistry, evaluate progress since his time, and report current research in this active field.

- Personal recollections of Alfred Werner
- The Werner-Jørgensen controversy
- Werner and cobalt complexes
- Nomenclature of coordination compounds
- Coordination in the second sphere
- Masking of ligand reactivity
- Linkage isomerism
- Chemistry of cyclobutadiene-iron tricarbonyl and many other topics.

661 pages with index      Cloth bound      (1967)  
postpaid in U. S. and Canada; plus 20 cents foreign and PUAS.

\$15.00

ADVANCES IN CHEMISTRY SERIES **62**

Set of L. C. cards free with library orders.

**Other books in the ADVANCES IN CHEMISTRY SERIES on Inorganic Chemistry include:**

**No. 54 Advanced Propellant Chemistry.** Primarily directed toward the search for new oxidizers. Twenty-six papers survey theory of advanced oxidizers, oxygen oxidizers, fuels and binders, fluorine systems, and liquid systems.

290 pages with index      Cloth bound      (1966)      \$8.50

**No. 49 Mechanisms of Inorganic Reactions.** Ten lectures by top authorities with extensive discussion prepared and presented by 20 more authorities. Topics include ion association in octahedral complexes, bridging groups in electron transfer reactions, kinetic patterns of ligand reactivity, acid-base reactions in fused salts.

266 pages with index      Cloth bound      (1965)      \$8.00

**No. 42 Boron-Nitrogen Chemistry.** Thirty-two papers on theoretical and preparative aspects of molecules containing B-N bonds, including many heterocyclic ring compounds

330 pages with index      Cloth bound      (1964)      \$7.50

**No. 39 Nonstoichiometric Compounds.** Twenty-three papers survey the field and give new work on structural aspects of nonstoichiometric oxides, hydrides, chalcogenides, and miscellaneous compounds.

253 pages      Paper bound      (1963)      \$7.00

**No. 37 Reactions of Coordinated Ligands and Homogeneous Catalysis.** Directs attention to changes in ligand groups when they attach to metal ions and to the role of coordination compounds in organic syntheses

255 pages      Paper bound      (1963)      \$7.00

**No. 36 Free Radicals in Inorganic Chemistry.** Surveys methods for investigating inorganic free radicals and details studies on several species, including the new difluoramine radical.

175 pages with index      Paper bound      (1962)      \$7.00

**No. 32 Borax to Boranes.** Twenty-eight papers from symposia sponsored by the Boron Committee of the ACS Division of Inorganic Chemistry during the peak years of interest in boron chemistry. Covers history and personalities in the field, chemistry of boron and its compounds, including the superfuels.

244 pages      Paper bound      (1961)      \$5.00

**No. 21 Ozone Chemistry and Technology.** Sixty papers from the International Ozone Conference cover: ozone chemistry, high concentration ozone, organic chemistry of ozone, ozone analysis and technology, atmospheric ozone, formation in electrical discharge, toxicity, sterilization and water purification, reaction kinetics.

465 pages      Cloth bound      (1959)      \$7.00

**No. 19 Handling and Uses of Alkali Metals.** Nineteen articles on the chemistry, manufacture, and use of the alkali metals; five are devoted solely or partly to lithium, two to potassium, the remainder to sodium.

177 pages      Paper bound      (1957)      \$4.75

All books postpaid in U. S. and Canada; plus 20 cents foreign and PUAS.

## Physical and Inorganic Chemistry

### Covalent and Ionic Character in Ground and Excited States of Benzene

Mary Craig<sup>1a</sup> and R. Stephen Berry<sup>1b</sup>

*Contribution from the Department of Chemistry, Yale University, New Haven, Connecticut, and the Department of Chemistry and Institute for the Study of Metals, University of Chicago, Chicago, Illinois 60637. Received January 16, 1967*

**Abstract:** Various wave functions for the ground ( $^1A_{1g}$ ) and low-lying excited states of benzene were examined by projecting onto them the valence-bond functions corresponding to Kekulé, Dewar, and Coulomb-stabilized ionic structures. The results show large (75%) contributions from singly ionic structures, 40–50% Kekulé structure for the ground state, and 30–40% covalent character to the  $^1B_{2u}$  state. The molecular wave functions are also examined for benzene distorted to a “cyclohexatriene” structure, particularly to determine the relative contributions of the two (now nonequivalent) Kekulé structures. The more favored or short double-bond structure increases its contribution about 25%, and the less favored structure decreases by about the same fraction. The relative change in Kekulé contributions and in corresponding pairs of ionic functions are the most significant changes associated with the distortion.

The quest for usefully accurate molecular wave functions has clearly reached a fruitful plateau. Wave functions now available for diatomic and small polyatomic molecules are sufficiently accurate to permit the calculation of a large variety of the ground-state properties of interest in traditional chemistry. These functions are not only numerically accurate; through the medium of contour maps,<sup>1</sup> they provide us with clear intuitive physical understanding of the variation of wave functions from state to state and from molecule to molecule. The collection of results, taken together, offers a happy rejoinder to the pessimistic reservations that were heard during the earliest years of the computer era.

To add to the information obtainable from orbital total wave-function contours, we felt that we could gain further insight into molecular behavior from another type of analysis. This analysis, with origins in traditional interpretations of electronic structure, is nevertheless still part of the chemist's vocabulary and perhaps a meaningful contributor to his chemical

intuition. Specifically, we refer to the determination of covalent and ionic character, as represented by valence-bond functions.

The basic idea is this: each valence-bond function represents a kind of physical behavior which we “understand” or can use for the interpretation of chemical behavior. The true molecular wave function  $\Omega$  or a reasonable approximation of it can be represented by a sum of contributions from a set of valence-bond (VB) functions, or from any complete basis set of functions, according to the principle of superposition. If the set happens to be a set of VB functions, we conventionally call the phenomenon of superposition “resonance.” If each function in the basis set is normalized to unity, then the coefficient or amplitude of a function is a measure of its contribution to the exact or approximate function  $\Omega$  under consideration; specifically, the absolute square of the coefficient of the basis function  $\Psi_j$  is the fraction of  $\Omega$  which is composed of  $\Psi_j$ .

We should explain and review just a little more of what the approach does and does not imply. First, it is very important to recognize that valence-bond

1 A. C. Wahl, *Science*, 151, 961 (1966); K. Ruedenberg, private communication.

wave functions are very highly correlated functions, with respect to both space and spin. A valence-bond analysis is not a population analysis in the sense that molecular orbital functions give population analyses; with valence-bond functions one can ask questions like "In a triplet state of benzene, what is the probability that, if one of the unpaired electrons is one atom 1, we will find the other on atom 4, while the remaining  $\pi$  electrons are in 2-3 and 5-6 bonds?" In other words, a valence-bond analysis is a very specific sort of analysis of electron correlation.

Second, we must remember that traditional valence-bond functions are not orthogonal to each other. This mathematical relationship between the functions has its parallel in physical terms; thus, the physical conditions represented by two valence-bond conditions are not in general mutually exclusive conditions. A covalent bond carries some ionic character in the traditional valence-bond representation. This nonorthogonality and the complexity of physical interpretation that accompanies it has two sources. One is the nonorthogonality of the basic atomic orbitals on different atoms; the other, much more bothersome for interpretive purposes, is due to the overcompleteness of the set of valence-bond structures. The first problem can be eliminated by generating a set of orthogonalized atomic orbitals, e.g., equivalent orbitals, and using these as basis functions. One necessarily delocalizes an orbital on one atom when one orthogonalizes it to an orbital on another atom. Consequently this orthogonality is obtained at the expense of a little intuitive understanding, at least insofar as our understanding of valence-bond structures are associated with localized orbitals. The other type of nonorthogonality has been discussed, for example, in connection with the question of resonance in butadiene.<sup>3</sup> It comes from the fact that one can in general draw more structures for a molecule than the number of *independent* functions, just as one can draw more than two vectors on an array of point in a plane. Yet just as any vector on the array can be represented with any two independent (nonparallel) vectors, any of the possible valence-bond structures of a molecule can be expressed in terms of some small number of independent structures. Thus for benzene's  $\pi$  electrons there are twelve possible nonionic singlet VB structures, but only six (any six) are independent. And with this overcompleteness comes the nonorthogonality problem: although we may choose six independent functions, in general these are not orthogonal; if we make them orthogonal, only one function of the orthogonal set can be chosen to represent a single valence-bond structure. We are forced either to give up orthogonality and to make our individual functions easily interpretable, or to make the functions orthogonal and therefore mutually exclusive, but accept basis functions that do not represent single structures.

The foregoing discussion is of course simply a review of some of the ramifications of valence-bond methods that have been long recognized in the literature of wave-function calculations. However, it seemed desirable to refresh our memories of some of these ramifications because of the possible misinterpretations which might arise if they are overlooked.

We have selected several representative wave functions for the six  $\pi$  electrons of benzene and projected onto these functions a number of suitably symmetrized valence-bond (VB) structure functions. The squares of these projections are the numbers of interest to us here; the square of the projection of a VB structure function  $\Psi$  onto an "accurate" six-electron function  $\Omega$ , namely,  $|\langle \Omega | \Psi \rangle|^2$ , is the fraction of  $\Omega$  which is made of  $\Psi$ . An analysis of this kind could have been performed by calculating the molecular wave function with a VB basis set, but the projection procedure is far more efficient, in view of the availability of rather good wave functions.

We have chosen to examine the  $\pi$  electrons of benzene for three reasons. First, we wished to find the relative importance of the Kekulé (or better, perhaps, Thiele) structure and of the ionic structures having the greatest Coulomb stabilization. Second, we wanted to learn how these contributions to the ground and low-lying excited states differed. Third, we were interested in the behavior of the electron pairing with molecular vibration, and particularly in the relative contributions of the two Kekulé structures when the bond lengths of the ring alternate between the values appropriate to "pure" double and single bonds.

The first reason was prompted by the results of a similar analysis of ground-state wave functions of butadiene.<sup>3</sup> The butadiene functions were naturally composed of 70-88% of the normal covalent structure, but, surprisingly, contained over 40% of the  $C^+C-C^+C^-$  structure. Such numbers raised questions in our minds of the role of multiply ionized structures in benzene. Craig<sup>4</sup> had actually carried out calculations with a VB basis but had restricted his functions to the Kekulé, Dewar, and singly ionized structures, including ionic Dewar structures. In light of the butadiene results, we chose to evaluate the projections of a somewhat different set, namely, the appropriately symmetrized combinations of structures 0-4. We shall refer to a

VB function representing a single diagram like those of 0-4 as a *primitive* VB function. A linear combination of physically equivalent primitive VB functions which transforms as an irreducible representation of the molecular point group is called a *symmetrized* VB function, or for convenience, simply a VB function.

The second part of this study is a comparison of the VB composition of the  $^1A_{1g}$  ground state with various VB contributions to the lower excited states. We have calculated the contributions of structures 0-3 to the  $^1B_{1u}$  and  $^1B_{2u}$  states, the states responsible for benzene's absorption bands in the 2400- and 2000-Å regions. We have also examined briefly the corresponding triplets, looking particularly at the roles of

<sup>a</sup> = 1.393 Å.

es 5 and 6. Note that 6 is the triplet analog of structure 4.

The third part of the analysis was stimulated by the notion that benzene's normal vibration of  $b_{2u}$  symmetry carried the molecule into a geometry appropriate to a cyclohexatriene structure.<sup>5</sup> If the C—C distances in a hypothetical "cyclohexatriene" are 1.465 and 1.335 Å,<sup>6</sup> then the benzene ring is roughly 15% of its time distorted enough to pass the cyclohexatriene geometry. The rather next question was this: to what degree do the rings respond to a cyclohexatriene geometry by changing themselves according to a *single* Kekulé structure? When the C—C bonds alternate in length 1.465 and 1.335 Å, what are relative contributions of the two Kekulé structures?

## Description of the Calculations

In presenting the results of the analysis, let us use the "accurate" wave functions we used. The details of the method of calculation are given in Appendix. For the  $1A_{1g}$  ground electronic state of the undistorted ( $D_{6h}$ ) benzene molecule, we used three different configurations, denoted by the letters a, b, and c: "a" is the configuration, based on atomic self-consistent field (SCF) orbitals of carbon;<sup>7</sup> "b" is a single configuration, based on Clementi's full molecular SCF function for all electrons of benzene,<sup>8</sup> which is probably the best available *uncorrelated* wave function for benzene; and "c" is the 22-term configuration interaction function of Moskowitz and Barnett based on the Slater function representations of the atomic orbitals.<sup>9</sup> This function does account for correlation but suffers from the limitation of a single Slater orbital representation. We shall use these three representations of the ground-state function as  $1A_{1g}-a$ ,  $1A_{1g}-b$ , and  $1A_{1g}-c$ , respectively. Unfortunately no function is yet available which combines the use of accurate atomic orbitals, as in b, with configuration interaction as in c.

In the excited states we examined the following functions, which we denote simply by the state designation and approximation: for the  $1B_{2u}$  state, all three approximations,  $1B_{2u}-a$  (based on atomic SCF orbitals),  $1B_{2u}-b$  (based on Clementi's full molecular SCF function), and  $1B_{2u}-c$  (Moskowitz' 13-term configuration interaction function for this state); and for the  $1B_{1u}$  state, triplets  $1B_{1u}$  and  $1B_{2u}$ , only the configuration interaction functions of Moskowitz, *i.e.*, the functions cor-

responding to approximation c, which have 16, 13, and 18 molecular orbital configuration basis functions, respectively.

For the distorted molecule, whose symmetry is  $D_{3h}$ , we used the  $2p\pi$  atomic SCF orbital basis. With these, we carried out a variational calculation to determine a best set of molecular orbitals. Specifically, when the molecular symmetry is reduced from  $D_{6h}$  to  $D_{3h}$ , the  $e_g$  and  $e_u$  orbitals all become  $e''$  orbitals ( $e''$  and  $e''_*$ ) and can mix, in pairs. We therefore replace the lowest configuration with a simple variational function

$$(a_{2u})^2(e_{1g})^4 \longrightarrow (a'')^2(e'' \cos \omega + e''_* \sin \omega)^4$$

$D_{6h} \qquad \qquad \qquad D_{3h}$

and expand the new function in terms of simple configurations based on  $e''$  and  $e''_*$  functions. To find the optimum mixture of the  $e''$  and  $e''_*$  orbitals, we need only diagonalize a  $2 \times 2$  one-electron Hamiltonian (see Appendix 2).

## Results

**A. Ground State.** Table I contains the values of squares of projections onto the ground state of functions representing structures 0–4. The primitive Dewar structure 4 was done only for the configuration interaction (CI) function  $1A_{1g}-c$ ; this is of little concern because it was really wanted only for comparison with the triplets. We remind the reader that the VB functions are highly nonorthogonal, so that the sums of the squares of the projections will in general be much larger than unity.

The first two rows of Table I are extremely similar, for a very simple reason. The  $\pi$ -molecular orbitals of  $D_{6h}$  benzene are fixed entirely by symmetry, and the composition of these orbitals in terms of VB functions is thereby determined. The only differences between the first row and the second in these two tables arise from the differences in the atomic overlap. The corresponding values for the single Slater function set without configuration interaction were also generated during the computation of the projections onto Moskowitz–Barnett functions. These are also quite similar to the first two rows, but about 10% smaller because of the smaller overlaps of the Slater basis set.

The amount of polar character in the benzene ground state is rather striking. Even after configuration interaction the  $1A_{1g}$  function retains a large portion of its singly ionic structure. The total covalent contribution increases considerably with CI, apparently at the expense of the doubly and especially the triply ionic function. We must exercise a little care in attributing an increase in one function to a decrease in another, both because of the nonorthogonality problem and because we have examined only a few structures. the analogy of the butadiene calculation,<sup>4</sup> we may expect the Slater function calculation of Moskowitz and Barnett to *underestimate* the amount of ionic character because of the inherently large estimate of the energy required to form a  $C^+C^-$  pair in this basis set.

**B. Excited Singlets.** Some of the VB structures are naturally excluded by symmetry considerations from contributing to particular excited states. For example, the two Kekulé structures can give only  $A_{1g}$  and  $B_{2u}$  combinations, and so are excluded from the  $B_{1u}$ ; the triply ionic structure (3) and its counterpart can give a sum and difference with  $A_{1g}$  and  $B_{1u}$  symmetry, but no  $B_{2u}$ ; the Dewar structure (4) cannot contribute  $B_{2u}$  either. These relations provided useful checks of the computational machinery.

In Table II we see both an analysis of various functions representing the  ${}^1B_{2u}$ , and, in the last line, the CI result alone for the  ${}^1B_{1u}$ . The physical situations in these two states are quite strikingly different; the lower energy  $B_{2u}$  is almost entirely covalent, while the  $B_{1u}$  has considerable doubly and triply ionic character.

**Table II.** Squares of Projections of VB Functions for Benzene in  ${}^1B_{2u}$  and  ${}^1B_{1u}$  States in Equilibrium Configuration\*

VB function	Primitive $\Psi_0$	Symmetrized $\Psi_0$	Symmetrized $\Psi_1$	Symmetrized $\Psi_2$	Symmetrized $\Psi_3$
${}^1B_{2u}$ -a	0.149	0.439	0.844	0.520	0
${}^1B_{2u}$ -b	0.147	0.432	0.840	0.512	0
${}^1B_{2u}$ -c	0.320	0.907	0.525	0.116	0
${}^1B_{1u}$ -c	0	0	0.562	0.611	0.215

\* Equilibrium, that is, for the ground state, with  $R = 1.393$  Å.

Note that symmetry alone forces the  ${}^1B_{2u}$  function to have a large amount of singly and doubly ionic character, but that CI reduces these considerably. The Moskowitz-Barnett single configuration, not shown in Table III, gives almost 0.8 for the symmetrized  $\Psi_1$ , so the reduction is not an artifact of the orbital basis set.

**C. Triplet.** The triplet result can be described very briefly. Symmetry excludes the nonionic structures 5 and 6 from the next-lowest triplet, the  ${}^1B_{2u}$ , but not from the lowest triplet, the  ${}^3B_{1u}$ . The primitive function representing structure 5 contributes 26% of the total function  ${}^3B_{1u}$ -c, and the Dewar-like or quinoid triplet, 40% of the same function. Recall from Table I that the ground state has 35% of the primitive Dewar structure. We interpret this to mean that the lowest triplet state may have a little more quinoid character than the ground state, but not vastly more.

**D. Distorted Benzene.** The results in the first line of Table III exhibit an interesting contrast to the first two lines of Table I. Note that it is with the *second* lines of Tables I and II, for  ${}^1A_{1g}$ -b and  ${}^1B_{2u}$ -b, that the

calculations of Table III should be compared, and not the third lines. No CI function is available for the distorted species, and it was our feeling that our one-parameter variation of the SCF function would give a sufficiently accurate measure of the *relative change* in the contributions of the two Kekulé structures. The total "symmetrized  $\Psi_0$ " in column 3 of Table III is based on the projection of the sum of the functions in the first two columns and is the equivalent of a Thiele structure in the same sense as the symmetrized  $\Psi_0$  of Table I. The value of 0.399 is essentially the same as the values of 0.395 for the symmetrized  $\Psi_0$  function on  ${}^1A_{1g}$ -a in Table I. However, the primitive  $\Psi_0$  in  $D_{6h}$  symmetry gives a value for  $|\langle \Psi_0 | {}^1A_{1g}$ -a  $\rangle|^2$  of 0.260; the two corresponding structures in our  $D_{3h}$  structure give essentially this average value, but the expected change in the relative contributions of these functions does actually occur. The contributions of the two covalent structures change, one upward and the other downward, by roughly 25%. The change is not startling, but it is very significant. By contrast to the change in the two Kekulé functions, the triply ionic contribution,  $\Psi_3$ , does not change dramatically when the  $C_6$  ring is distorted to  $D_{3h}$  symmetry. This lack of change is particularly evident in the  ${}^1B_{2u}$  excited state, where triply ionic character is forbidden in sixfold symmetry but allowed in  $D_{3h}$ . The actual amount of triply ionic character in  ${}^1B_{2u}$ -a, in the  $D_{3h}$  form, is only 0.01%, so that the distortion is a very small perturbation so far as "triple-ionization" is concerned.

We shall close with a remark about a limitation of a method such as the one used here. The concept of a valence-bond structure is meaningful only in terms of a specific set of atomic orbitals. As such, it can be used to analyze only those wave functions based on a single, well-defined set of atomic orbitals. The method will not be applicable to configuration interaction wave functions based on configurations each of which has its own uniquely determined basis set, chosen for example to make each configuration satisfy self-consistent field and orthogonality relationships.

**Acknowledgments.** We thank Enrico Clementi and Jules Moskowitz for their kindness in supplying us with wave functions, and Paul Cade, Andrew Hazi, and Joshua Jortner for their assistance in evaluating integrals. We also thank Gerhard Closs for suggesting that we calculate the quinoid or Dewar projections. This work was supported by the National Science Foundation.

#### Appendix. 1. Method of Computing Projections

$\Omega$  represent the "accurate" wave functions, which are expressed in terms of orthonormal orbitals  $\psi$ . Then we write the transforming  $\Psi$  in terms of  $\Omega$ 's as a series of matrix operations

$$\Psi = \text{VDS}^{-1}\text{C}\Omega \quad (1)$$

is the configuration interaction matrix (the exception for the Moskowitz set  $\Omega_c$ );  $\text{S}^{-1}$  is the matrix which is the inverse of the matrix generating functions from single MO determinants; matrix transforming single MO determinants into properly symmetrized VB functions. Neither  $\text{D}$  nor  $\text{V}$  is unitary because of the nonorthogonality of VB functions. The inversion of  $\text{S}^{-1}$  and  $\text{V}$  is straightforward. The inversion of  $\text{S}^{-1}$  and  $\text{V}$  is straightforward. The inversion of a matrix whose construction is described by Moffitt.<sup>10</sup> The transformation from MO's  $\psi$  is given in terms of a unitary matrix and a diagonal matrix  $\text{d}$  (eq 2). We consider only the

$$\varphi = \text{d}u\pi = \gamma\pi \quad (2)$$

which the  $z$  component of spin is zero, so that as many electrons with spin  $+\hbar/2$  as with spin  $-\hbar/2$ . Then the indices 1, 2, and 3 are reserved for orbitals with  $+\hbar/2$   $z$  spin and indices 4, 5, and 6 for orbitals with  $-\hbar/2$   $z$  spin. Then the matrix element connecting a determinant based on MO's  $\alpha_i$ , with a determinant based on AO's  $\beta_i$ , ... , is written as shown in eq 3.

$$\begin{aligned} \frac{u_{\alpha_1 \dots \alpha_{2n}}^{\beta_1 \dots \beta_n} u_{\alpha_{n+1} \dots \alpha_{3n}}^{\beta_{n+1} \dots \beta_{2n}}}{d_{\alpha_1 \dots \alpha_{3n}}} \\ = \frac{|u_{\alpha_1 \dots \alpha_n}^{\beta_1 \dots \beta_n}| |u_{\alpha_{n+1} \dots \alpha_{3n}}^{\beta_{n+1} \dots \beta_{2n}}|}{d_{\alpha_1 \dots \alpha_{3n}}} \end{aligned} \quad (3)$$

of

$$u_{\alpha_1 \dots \alpha_n}^{\beta_1 \dots \beta_n}$$

Moffitt, *Proc. Roy. Soc. (London)*, **A218**, 486 (1953).

denotes the determinant formed from the minor of the  $\text{u}$  matrix from the elements indicated. The quantities  $d_{\alpha_i}$  are the  $\alpha_i$ - $\alpha_i$  elements of the diagonal matrix  $\text{d}$ .

The entire transformation was set up for machine computation. For a given state and molecular geometry, the choice of functions to use for the  $\Omega$  set was reflected only in the set of atomic overlap integrals one put into the input deck. For reference, the overlaps are given in Table IV.

## Appendix 2. Estimation of the Distorted Ground-State Wave Function

In the  $\text{D}_{3h}$  configuration of benzene, the optimum mixture between the  $e''$  and  $e''_*$  orbitals is found by first orthogonalizing the pair of mixed orbitals and then minimizing the energy of the mixed pair. For example in the  $\text{D}_{3h}$  representation  $e''$ , the  $e_{1g}$  function,  $\phi = C_1(\pi_1 + \pi_2 - \pi_4 - \pi_5)$ , becomes nonorthogonal to the function  $\phi_2 = C_2(\pi_1 + \pi_2 - 2\pi_3 + \pi_4 + \pi_5 - 2\pi_6)$ ; their overlap integral  $S_{12}$  is proportional to the difference between the overlap integrals  $(\pi_1 | \pi_2)$  and  $(\pi_2 | \pi_3)$ . The secular equation was set up in terms of  $\phi_1$  and the function,  $[\phi_2 - (\phi_1 | \phi_2)\phi_1]$ , Schmidt-orthogonalized to  $\phi_1$ . The elements of the secular determinant are

$$H_{11}$$

$$H_{12}' = H_{12} - S_{12}H_{11}$$

$$H_{22}' = H_{22} - 2S_{12}H_{12} + S_{12}^2H_{11}$$

where

$$H_{11} = d_1^2 u_{1i} u_{1j} h_{ij} \quad h_{ij} = (\pi_i | \mathcal{H} | \pi_j)$$

$$H_{12} = d_1 d_2 u_{1i} u_{2j} h_{ij}$$

$$H_{22} = d_2^2 u_{2i} u_{2j} h_{ij}$$

using the Einstein summation convention. Elements  $h_{ij}$  were taken as  $h_{ii} = 11.54 \text{ eV} =$  the valence-state ionization potential,<sup>11</sup> and  $h_{ij}$  as resonance integrals obtained by numerical integration of a Goepfert-Mayer-Sklar core potential for the different bond lengths involved.<sup>12</sup>

# Details of the Steric Interaction in Mono-*ortho*-substituted Nitrobenzene Anion Radicals<sup>1a</sup>

Ted M. McKinney and David H. Geske<sup>1b</sup>

Contribution from the Department of Chemistry, Cornell University, Ithaca, New York. Received August 25, 1966

**Abstract:** Previously reported electron spin resonance studies of substituted nitrobenzene anion radicals have provided substantial structural information. The present esr study of nitrobenzene anion radicals with *o*-alkyl substituents permits structural assertions based on both nitrogen and  $\beta$ -proton isotropic coupling constants. As an ancillary matter coupling constants (including thermal coefficients) for nitrobenzene anion radicals with *p*-alkyl substituents are presented. Data for 4- and 5-nitroindan anion radicals, where the methylene protons are essentially fixed with respect to the benzene ring, serve to substantiate the angular dependence of the  $\beta$ -proton coupling constants.

The study of organic free radicals by esr has provided substantial structural and conformational insights.<sup>2</sup> One such example is the work on steric hindrance in nitroaromatic anion radicals. In particular, the effect of mono- and di-*ortho* substituents with threefold symmetry [ $Y = -CH_3, -C(CH_3)_3$ ] has already been reported.<sup>2-5</sup>

The examination of nitrobenzene anion radicals with unsymmetrical mono-*ortho* substituents [ $Y = -CH_2CH_3, -CH(CH_3)_2$ ] is reported here. This study is directed to the question of the detailed orientation of the substituent group and of the nitro group with respect to the benzene ring. For the purposes of comparison, the *para* derivatives were also examined. Since coupling constants for the methylene and methine protons of the substituent group are the basis for conformational assertions, it was of interest to examine the temperature dependence of these coupling constants. The examination of two nitroindan anion radicals was relevant because the methylene hydrogens are essentially fixed with respect to the benzene ring.

## Experimental Section

2- and 4-ethylnitrobenzenes, as obtained from Aldrich Chemical Company, Inc., were purified by preparative vapor phase chromatography, using a 10-ft column of 20% Carbowax on Chromosorb P. Refractive indices measured at 20° were 1.5353 and 1.5451 for the *ortho* and *para* isomers, respectively. The reported values are 1.5352 and 1.5459, respectively.<sup>6</sup>

4-Isopropylnitrobenzene was prepared by nitration of cumene (Phillips Petroleum "Pure Grade") according to the procedure of Nelson and Brown.<sup>7</sup> The product boiled at 92° at a pressure of

approximately 10 mm and had a refractive index of 1.5369 at 20° which was identical with the literature value.<sup>6</sup> The 2-isopropylnitrobenzene was a gift of Professor B. M. Wepster, Delft, The Netherlands.

Nitration of indan (Aldrich) using the procedure described by Newton<sup>8</sup> yielded 4- and 5-nitroindan. The isomers were separated by preparative vapor phase chromatography, using the same conditions employed for the 2- and 4-ethylnitrobenzenes. The melting point of 4-nitroindan was 42.5° and that of 5-nitroindan was 40°. The literature values are 44–44.5° and 40–40.5°, respectively.<sup>8b</sup>

Acetonitrile and dimethylformamide were purified by previously described procedures.<sup>9</sup> Tetrapropylammonium perchlorate for use as supporting electrolyte was recrystallized three times from water.

The anion radicals were generated electrochemically using the *intra muros* technique.<sup>9</sup> Variable-temperature measurements were made using the Varian V-4557 variable-temperature accessory. Esr signals were normally recorded as the first derivative of the absorption. This mode of presentation usually gave sufficient resolution for complete assignment of the spectrum. However, in some instances the proton hyperfine interactions were of such small magnitude compared to the line width that accurate measurements were impossible. Display of the second derivative greatly facilitated measurements of small splittings and of lines with overlapping components.

Reported coupling constants are averages of at least three individual measurements. For completeness, the parameters used in computed spectra are included in the appropriate figure captions. All computed spectra were simulated with a Lorentzian line shape. Details of electrochemical<sup>10</sup> and electron spin resonance measurements<sup>11</sup> have been described previously.

## Results

In order to provide a basis for direct comparison of coupling constants with data secured in the earlier study,<sup>5</sup> acetonitrile (AN) was used as the solvent in this work also. Spectra were also obtained in dimethylformamide (DMF). In general, these spectra were more highly resolved and the lines were narrower than those obtained in AN. Assignment of the spectrum in DMF was often more straightforward and facilitated assignment of the spectrum obtained in AN. The nitrogen coupling constant for a particular anion radical is somewhat larger in AN than in DMF,<sup>12</sup> and there is a corresponding decrease in spin density at the *para* ring position. This reorganization of spin density dis-

Low-field one-half of esr spectrum obtained by reduction of 0.11 mM solution of 2-ethylnitrobenzene in DMF. (b) Spectrum computed using the values (in gauss) 3.92 (1 proton), 1.125 (1 proton), 3.34 (1 proton), 1.805 (2 protons), 11.46 (1 nitrogen), a line width of 1.06, and 0.005-gauss increments.

upon changing the solvent medium was a factor in the assignment of proton coupling to particular molecular positions.

ESR data for the compounds examined in this study are given in Table I along with data for related compounds studied earlier. They are all close to 2.0 but they were not explicitly

All of the compounds in Table I meet the condition for reversible, one-electron reduction, namely,  $E_{1/2} - E_{1/2} \approx -56$  mv. The different constants also indicate the transfer of an electron.

Proton coupling is the dominant feature of the ESR spectra reported here. The proton constants were assigned by analogy to the assignment of the *m*-monodeuteronitrobenzene,<sup>5</sup> but in certain instances there is uncertainty as to which nucleus is responsible for a given constant. Hence, the assignments are discussed below.

**4-Ethylnitrobenzene.** The spectrum of the 4-ethylnitrobenzene anion radical in DMF had a line width of 0.33 gauss and was readily assigned using the coupling constants shown in Table I. By analogy to the nitrobenzene radical, the smallest splitting constant was assigned to the *meta* protons. The 3.37-gauss splitting constant for the equivalent nuclei with a spin of  $1/2$  was assigned to the coupling constants for the *ortho* protons of nitrobenzene and *p*-nitrotoluene radicals<sup>5</sup> and were assigned to the *ortho* protons. This is supported by the observation of the same value in 4-nitrobenzene anion where there is no possibility in assignment of *ortho* and *para* constants since the latter gives rise to a doublet.

The remaining 2.96-gauss triplet was assigned to the methylene protons of the ethyl group. The data show that the protons of the *para* substituent of ethylnitrobenzene radical do indeed have a coupling constant in DMF than in AN, and this is due to the assignment of coupling constants to particular positions. The coupling constants for this radical in ethanol<sup>13</sup> and aqueous acetone<sup>14</sup> are available for comparison.

Figure 2. (a) Low-field one-half of esr spectrum obtained by reduction of 0.11 mM solution of 2-isopropyl nitrobenzene in AN. (b) Spectrum computed by using the values (in gauss) 3.565 (1 proton), 3.175 (1 proton), 1.125 (3 protons), 11.46 (1 nitrogen), a line width of 0.3, and 0.005-gauss increments.

**2-Ethylnitrobenzene.** Figure 1 shows the low-field half of the spectrum of the 2-ethylnitrobenzene anion radical in DMF together with a computed spectrum. This is a relatively complicated spectrum since the ring protons are not strictly equivalent in pairs. The close similarity of the experimental and computed spectra is substantial evidence for the validity of the assignment. By analogy to the nitrobenzene spectrum, the two smallest coupling constants were assigned to the positions *meta* to the nitro group. The proton coupling constants for the 3 and 5 positions were slightly different. There is no basis for distinguishing which position is associated with the larger constant, a fact indicated in Table I by bracketing the constants.

The triplet proton splitting was immediately assignable to the methylene protons of the ethyl substituent since they are the only two protons in the radical which are fully equivalent. The remaining two proton doublets were assigned to positions *ortho* and *para* to the nitro group; by analogy to the nitrobenzene radical, the larger value was assigned to the *para* ring proton. Moreover, this splitting showed the larger solvent variation.

**4-Isopropyl nitrobenzene.** Since the methine proton is the only nucleus in the isopropyl group which shows a resolvable splitting, the ESR spectrum for the 4-isopropyl nitrobenzene anion radical bears a formal resemblance to that for the nitrobenzene anion radical. Accordingly, the smallest coupling constant was attributed to the *meta* protons. Assignment of the 1.8-gauss constant to the methine proton is unequivocal. The line width for the ESR spectrum in DMF was 0.33 gauss. The coupling constants for this anion radical in aqueous acetone are also given in Table I.

**2-Isopropyl nitrobenzene.** Figure 2 shows the low-field half of the experimental spectrum for the 2-isopropyl nitrobenzene anion along with a spectrum computed using the coupling constants given in the figure caption.

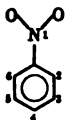

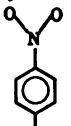

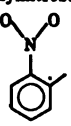

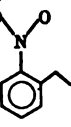

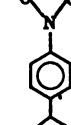

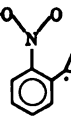

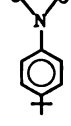

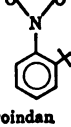

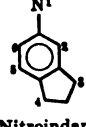

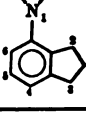

The outstanding features of the proton hyperfine structure are the extreme low-field lines which indi-

## I (Footnotes)

half-wave potentials are reported for acetonitrile solution with respect to the aqueous saturated calomel electrode. Data are tabulated by the least negative half-wave potential for each compound. <sup>a</sup> Diffusion current constant,  $i_d/m^{1/2}t^{1/2}C$ , where the maximum diffusion current  $i_d$  is measured in microamperes,  $m$  in milligram per second,  $t$  is seconds, and  $C$  in millimoles per liter. <sup>b</sup> Notation: A, acetonitrile; D, dimethylformamide; AA, 10–15% aqueous acetone; E, ethanol. <sup>c</sup> Nitrogen coupling constant. <sup>d</sup> Data from ref 9. <sup>e</sup> Data from P. H. Rieger and G. K. Fraenkel, *J. Chem. Phys.*, **39**, 609 (1963). <sup>f</sup> Data for AA from ref 14. <sup>g</sup> Data for E from ref 13. <sup>h</sup> Data for A. H. Maki and D. H. Geske, *J. Am. Chem. Soc.*, **83**, 1852 (1961). <sup>i</sup> Coupling constant for three equivalent nuclei with spin of  $1/2$ . <sup>j</sup> Data from ref 5. <sup>k</sup> Coupling constant for two methylene protons of ethyl group at this position. <sup>l</sup> After completion of this work the same coupling constants were reported by E. G. Janzen and J. L. Gerlock, *J. Org. Chem.*, **32**, 820 (1967). <sup>m</sup> The ring protons *ortho* to the nitro group are nonequivalent, but there is no straightforward way of determining which position has the larger coupling constant. <sup>n</sup> Coupling constant from the methine proton of the isopropyl substituent at this position. <sup>o</sup> No splitting resolved from the *t*-butyl group. <sup>p</sup> Coupling constants for methylene protons.

the presence of quartet splittings with intensity ratios of approximately 1:3:3:1. Since there are not symmetrically equivalent protons in the molecule, it implies that the coupling constant for the methine proton of the isopropyl group is accidentally nearly the same as that for the two ring protons *meta* to the nitro group. The larger of the two remaining doublet splittings is assigned to the *para* ring proton by analogy to nitrobenzene case. Furthermore, this coupling constant increases when the solvent is changed from acetonitrile to DMF. The other doublet is assigned to the proton *ortho* to the nitro group.

Figure 3. (a) Low-field one-half of ESR spectrum obtained by reduction of 0.96 mM solution of 5-nitroindan in DMF. (b) Spectrum computed by using the values (in gauss) 3.52 (1 proton), 3.22 (1 proton), 1.09 (1 proton), 5.42 (2 protons), 1.41 (2 protons), 10.34 (nitrogen), a line width of 0.16, and 0.005-gauss increments.

***t*-Butylnitrobenzene.** Unresolved hyperfine structure from the nine methyl protons in the *t*-butyl group contributes to the line width in this spectrum. The assignment of the spectrum of this radical in acetonitrile earlier<sup>4</sup> distinguished no difference in coupling constants for the *ortho* and *para* ring protons. During the present investigation the spectrum was obtained in DMF. Use of a second derivative display revealed two different doublet splittings, the larger of which was assigned to the *para* ring proton. The difference was resolved between the *meta* proton coupling constants.

**Nitroindan.** Experimental and computed spectra of the anion radical of 5-nitroindan are given in Figure 3. Assignment of the larger of the two methylene proton coupling constants to the protons at the 4 position (numbering defined in Table I) is based on the larger

spin density at the *para* carbon atom. The two *ortho* proton coupling constants are distinguished as different; the arbitrary nature of the assignment between positions 2 and 6 is indicated in Table I by brackets.

**4-Nitroindan.** The experimental ESR spectrum for the anion radical of 4-nitroindan in DMF is shown in Figure 4 along with a computed spectrum. The quartet

Figure 4. (a) Low-field one-half of ESR spectrum obtained by reduction of 1.1 mM solution of 4-nitroindan in DMF. (b) Spectrum computed by using the values (in gauss) 4.015 (1 proton), 3.38 (1 proton), 4.93 (2 protons), 1.09 (3 protons), 9.80 (1 nitrogen), a line width of 0.14, and 0.005-gauss increments.

structure for the smallest coupling constant was attributed to accidental coincidence of the coupling constants for the *meta* ring and methylene protons (positions 3 and 5, Table I). The triplet splitting of 4.9 gauss has been assigned to the *o*-methylene protons, and the larger of the two remaining proton coupling constants was assigned to the *para* proton.

**Temperature Dependence.** Data for the temperature dependence of the alkyl proton coupling constants are given in Table II. Equation 1 describes the temperature dependence of the methine proton coupling constant,  $a_{iso}^H$ , in the 4-isopropylnitrobenzene anion

$$a_{iso}^H = 1.389 + (1.23 \times 10^{-5})T \quad (1)$$

radical as a function of absolute temperature,  $T$ , with a correlation coefficient of 0.994.

## Discussion

We wish to examine the above data with the intention of extracting those structural inferences which are warranted.

<sup>a</sup> Data for anion radicals in acetonitrile solution. <sup>b</sup> Number of measurements. <sup>c</sup> Uncertainties designated at the 95% confidence levels.

**Nitrogen Coupling Constants.** Attention is first of all focused on the nitrogen coupling constants. Previous work<sup>5</sup> has established that introduction of bulky substituent groups *ortho* and *di-ortho* to the nitro group in nitrobenzene anion radicals results in a substantial increase in the isotropic nitrogen coupling constant,  $a_N$ . Thus with acetonitrile as solvent,  $a_N$  increases from 10.3 gauss for nitrobenzene anion radical to 23.6 gauss for one conformational isomer of the 2,3,5,6-tetraisopropylnitrobenzene anion radical.<sup>11</sup> In qualitative terms, this increase in  $a_N$  can be regarded as the result of the transfer of spin density from the phenyl group to the nitro group as the nitro group is twisted out of the plane of the ring by *ortho* substituents. A rationalization of nitro group nitrogen coupling constants on the basis of semiempirically calculated nitrogen and oxygen  $\pi$ -spin densities has been developed by Rieger and Fraenkel;<sup>4</sup> twisting of the nitro group was accommodated in their molecular orbital calculations by a decrease of the carbon–nitrogen resonance integral. On the basis of examination of the anisotropic nitrogen coupling constants, Fox, Gross, and Symons<sup>15,16</sup> have suggested that twisting of the nitro group along the carbon–nitrogen axis is accompanied by pyramidal distortion of the nitro group.

The nitrogen coupling constants for the nitrobenzene anion radicals (Table I), where the 2-substituent (Y) is successively –H, –CH<sub>3</sub>, –CH<sub>2</sub>CH<sub>3</sub>, –CH(CH<sub>3</sub>)<sub>2</sub>, and –C(CH<sub>3</sub>)<sub>3</sub>, are 10.3, 11.0, 10.7, 11.5, and 14.9 gauss, respectively (in AN). The point of particular interest is that there is only a minimal effect on  $a_N$  for Y = methyl, ethyl, and isopropyl; for the symmetrical *t*-butyl group there is an abrupt increase in  $a_N$ .<sup>17</sup> We interpret these data as evidence that the 2-ethyl and 2-isopropyl substituents are oriented for *minimum* interaction with the nitro group. A simplified view would state that, if the ethyl and isopropyl groups were rotating freely, the  $a_N$  values would be expected to be the same as for the 2-*t*-butylnitrobenzene anion radical.

(15) J. M. Gross and M. C. R. Symons, *J. Chem. Soc., Sect. A*, 451 (1966).

(16) W. M. Fox, J. M. Gross, and M. C. R. Symons, *ibid.*, 448 (1966).

(17) As in earlier studies<sup>4</sup> comparison of the coupling constants for the *para*-substituted anion radicals with constants for nitrobenzene anion radical demonstrates the minor extent of the nonsteric effects of the *ortho* substituent. Although we have not secured esr data for the 4-*t*-butylnitrobenzene in AN and DMF, it is clear from the data in Table I for ethanol and aqueous acetone that the inductive effect of the *p*-*t*-butyl group is negligible.

The  $a_N$  of 10.5 gauss for the 4-nitroindan anion, where the methylene protons are essentially fixed in relation to the ring, is consistent with this interpretation.

Within this context it is of interest to examine  $a_N$  for several other *ortho*-substituted nitrobenzene anion radicals. In the *o*-nitrobiphenyl anion radical where  $a_N$  is 8.7 gauss in DMF,<sup>18</sup> a compromise of twisting the nitro group out of the plane of the ring and delocalization of spin density into the *ortho*-ring substituent much be reached. Essentially the same conclusions have been reached for the anion radical of 2-nitroterphenyl.<sup>19</sup> From the data of Carrington, Hudson, and Longuet-Higgins,<sup>20</sup> it is clear that the nitro group is hindered in the hydrogen adducts of the tetrafluoro- and pentafluoronitrobenzene anion radicals. However,  $a_N$  in the 2-fluoronitrobenzene anion radical<sup>20</sup> gives no evidence of steric hindrance.

**Alkyl Proton Coupling Constants.** Examination of the alkyl proton coupling constants in the *ortho*-substituted anion radicals for conformational implications requires a brief review of the angular dependence of transmission of spin density to  $\beta$  protons ( $\beta$  protons are defined as those protons on an  $sp^3$  carbon which is in turn bonded to a  $\pi$  system). This concern was initiated by the observation of methyl proton coupling constants in methylated semiquinones by Venkataraman and Fraenkel<sup>21</sup> in 1955.

Bersohn<sup>22</sup> proposed a hyperconjugative mechanism which involved the mixing of the methyl group pseudo- $\pi$  orbital with the  $\pi$  system on the adjacent trigonal carbon atom. Over the past 10 years an extensive literature has developed on the theory of  $\beta$ -proton coupling constants.<sup>22–32</sup> In the main, Bersohn's proposal of hyperconjugation has been substantiated. The point of interest for derivation of conformational information is the angular dependence of the  $\beta$ -proton coupling constants,  $a_\beta^H$ , as stated in eq 2 where  $\rho_{C'}$  is the  $\pi$ -electron spin density on the trigonal carbon, C', to

$$a_\beta^H = \rho_{C'}(B_0 + B \cos^2 \theta) \quad (2)$$

which the alkyl group is attached,  $B_0$  and  $B$  are constants, and  $\theta$  is the angle between the C'–C–H plane and the axis of the  $p_z$  orbital on the trigonal carbon atom. The value of  $B_0$  has been variously estimated as –1.1<sup>31</sup> and 4.33 gauss.<sup>32</sup> Estimates of  $B$  range from 40 to 53 gauss.<sup>34–36</sup>

on 2 has been widely used in the rationalization spectra of alkyl radicals in irradiated sol-

The first conformational assertions for radicals in solution were made by Stone and 1962. They interpreted the  $\beta$ -proton cou- constants<sup>41</sup> for a series of nitroalkane anion rad- cations of a preferred orientation of the alkyl alting from a finite barrier to rotation. Since groups in the nitroalkane anions are not ented  $a_\beta^H$  is actually a time-averaged quantity n eq 3, where  $\rho_N^\pi$  is the  $\pi$ -electron spin density rogen atom. Evaluation of the average quan-  $\theta$ ) in eq 3 was done quantum mechanically

$$a_\beta^H = \rho_N^\pi (B_0 + B(\cos^2 \theta)) \quad (3)$$

and Maki<sup>35</sup> under the assumption of a simple inusoidal barrier with a maximum barrier  $V_0$ . On the basis of evaluation<sup>42</sup> of this graphic representation of  $\langle \cos^2 \theta \rangle$  vs.  $V_0$  nted for the four different equilibrium cons- in Figure 5. For the 2-nitropropane ical,<sup>41</sup>  $V_0$  was estimated as 1.1 kcal mole<sup>-1</sup> Figure 5) as the equilibrium conformation. itroethane anion radical,<sup>41</sup>  $V_0$  was estimated cal mole<sup>-1</sup> with 2a (Figure 5) as the equilib- ormation. Temperature coefficients,  $da_\beta^H/dT$ , icted; however, the experimental data neces- st these predictions have never become avail- one has suggested that there are several rea- the calculated barriers "should not be taken isly."<sup>43</sup> In addition to the assumption of a rier, both estimated values of  $V_0$  are near the  $T$ ,  $\sim 0.6$  kcal mole<sup>-1</sup> at 298°K, a region where imate method of averaging is least accurate. ment to the work by Stone and Maki,<sup>35</sup> a f workers<sup>36,44-50</sup> have argued for preferred n of alkyl groups in radicals in solution on the 3. Of particular note is the work of Fessen- , evaluated eq 3 for a series of radicals,  $R\dot{C}H_2$ , is an alkyl substituent. Exact solution was ecause the reduced moment of inertia was ough to permit utilization of existing mathe- bles. The experimental values<sup>44</sup> of  $a_\beta^H$  for the radical over the temperature range  $-50$  to re in reasonable agreement with a calculated assuming a barrier of 295 cal mole<sup>-1</sup>. The re dependence for the propyl radical using a a 412 cal mole<sup>-1</sup> was in excellent agreement

with the experimental data. The equilibrium conforma- tions were 1b and 2b (Figure 5), respectively.

The 9-ethyl- and 9-isopropylxanthyl radicals studied by Sevilla and Vincow<sup>50</sup> are distinguished by the extent to which  $a_\beta^H$  values approach the expected limits (see Table III) for conformations 1a and 2a (Figure 5),

Table III. R Values for Nitroalkane Anion<sup>41</sup> and Alkylxanthyl<sup>51,52</sup> Radicals

$[CH_2CH_2NO_2]^-$	25.5	9.75	0.85
$[C_2H_5CH_2NO_2]^-$	24.8	9.98	0.87
$[CH_2CHNO_2CH_2]^-$	25.2	4.60	0.40
$[CH_2CHNO_2CH_2CH_2]^-$	24.7	3.19	0.28
9-Methylxanthyl		12.18	
9-Ethylxanthyl		6.22 <sup>b</sup>	0.51
9-Isopropylxanthyl		0.86 <sup>c</sup>	0.07

<sup>a</sup> Ratio of  $\beta$ -proton coupling constant to methyl proton coupling constant in parent radical. <sup>b</sup> Value for 110°. <sup>c</sup> Value for  $-10^\circ$ .

respectively.  $V_0$  for the ethylxanthyl radical has been estimated as 6 kcal mole<sup>-1</sup>.<sup>51</sup> An even larger barrier is indicated for the isopropyl radical.

In order to simplify the comparison of  $\beta$ -proton coupling constants within a series of related radicals such as the nitroalkane anions, it is convenient to define the quantity R in eq 4.  $a_\beta^H$  is the coupling con-

$$R = \frac{a_\beta^H}{a_{CH_3}^H} \quad (4)$$

stant for the  $\beta$  protons of the alkyl substituent, and  $a_{CH_3}^H$  is the coupling constant for the  $\beta$  protons of the corresponding methyl-substituted radical. The methyl group is usually regarded as freely rotating, i.e.,  $V_0 \sim 0$ ;<sup>52</sup> eq 5 is valid even with a barrier provided that transitions between potential minima are rapid.<sup>43</sup>

$$a_{CH_3}^H = \rho_1^\pi \left( B_0 + \frac{B}{2} \right) \quad (5)$$

With the definition of R in eq 4 it is not necessary to explicitly evaluate  $\rho_C^\pi$  in eq 2 or  $\rho_N^\pi$  in eq 3 as long as

(51) M. D. Sevilla, private communication.

(52) The barrier for the methyl group in nitromethane has been estimated as 6 cal mole<sup>-1</sup>.

Figure 6. Representation of conformations of adjacent nitro and alkyl groups.

they remain essentially constant within the series. Furthermore, if one assumes  $B_0 \ll B$ , there is no need to select a value for  $B$ . Under these assumptions the values of  $R$  for conformations 1a, 1b, 2a, and 2b in Figure 5 are 0, 2, 0.5, and 1.5, respectively, under conditions of infinite barrier. The relation between  $R$  and  $\langle \cos^2 \theta \rangle$  is as given in eq 6. To facilitate com-

$$R = 2\langle \cos^2 \theta \rangle \quad (6)$$

parison of  $R$  values for radicals in Table I, values of  $R$  for the nitroalkane anion radicals<sup>41</sup> and alkylxanthyls<sup>50,51</sup> are presented in Table III.

A substantial body of esr data for rigid radicals is available<sup>38,44,45,52,54</sup> to support the validity of eq 2. Nevertheless, we felt that it was appropriate to examine several nitroaromatic anion radicals where the  $\beta$  protons are essentially fixed in relation to the benzene ring.

The 4- and 5-nitroindan anion radicals are in this category. The experimental  $R$  values for the methylene protons in the *para* position (position 4, Table I) in the 5-nitroindan anion radical are 1.35 and 1.36.  $R$  for the *ortho* (position 2, Table I) methylene protons of 4-nitroindan anion radicals are 1.56 and 1.53. Since conformation 2b (Figure 5) describes both of these methylene groups, the theoretical  $R$  value is 1.50. One might choose to argue that the reduced value of  $R$  for the *para*-position methylene groups, 1.36 in 4-nitroindan anion radical, is evidence for some torsional motion of the methylene group, *i.e.*, axial-equatorial inversion. In the same context the closer coincidence of experimental  $R$  values in the 5-nitroindan with 1.50 would be regarded as evidence for a more rigid structure as a consequent of the adjacent nitro group. These

detailed assertions may not be fully warranted and should surely be viewed with caution. However, we do regard the data for the nitroindan radicals as reasonable evidence for the validity of eq 2.<sup>55</sup>

Turning now to consideration of data for the *p*-alkylnitrobenzene anion radicals, it is important to note the comment of Carrington and Todd<sup>48</sup> who suggested, on the basis of the data of Ayscough, Sargent, and Wilson<sup>12</sup> (Table I), that the preferred orientation of the ethyl group in 4-ethylnitrobenzene anion radical corresponds to 2a (Figure 5). Data for this anion radical in four solvent media are included in Table I. The  $R$  values (extreme right column, Table I) range from 0.74 to 0.80. If one accepts the Stone-Maki model,<sup>35</sup> the corresponding range of  $V_0$  is 0.9 to 0.55 kcal mole<sup>-1</sup> with 2a (Figure 5) as the equilibrium conformation.<sup>56</sup>

$R$  values calculated for the *p*-isopropylnitrobenzene anion radical from the data in this work and from the data of Kolker and Waters<sup>14</sup> (Table I) are 0.44 and 0.47, respectively. Within the Stone-Maki model this corresponds to a barrier,  $V_0$ , of 1.0 kcal mole<sup>-1</sup> and 1a (Figure 5) as the equilibrium conformation. The observed temperature coefficient,  $1.39 \times 10^{-3}$  gauss deg<sup>-1</sup>, may be compared with a calculated value of  $3.8 \times 10^{-3}$  gauss deg<sup>-1</sup>. There are several possible explanations for the discrepancy between observed and calculated temperature coefficients. One possibility is that the approximate solution<sup>35</sup> is inadequate. A more likely alternative is that the real barrier is more complex than the simple sinusoidal barrier assumed in the calculation.<sup>35</sup> In fact, there could even be a shallow potential minimum at  $\theta = 0^\circ$ . We conclude that it is not possible to specify in detail the nature of the potential barrier.

With the strong indication at hand that the *p*-alkyl substituents undergo anisotropic averaging, it is appropriate to examine data for the *o*-alkylnitrobenzene anion radicals. It should be clear at the outset that the *ortho*-substituted radicals no longer possess twofold symmetry; thus, there is no reason to suppose that the potential barrier experienced by the  $\beta$  protons and the nitro group has twofold symmetry.

Observation of a coupling constant for three equivalent methyl protons in the *o*-methylnitrobenzene anion radical provides no information about the barrier to rotation. It does establish that transitions between potential minima are rapid<sup>57</sup> (*cf.* eq 5). Janzen and Gerlock<sup>58</sup> find line-width effects in the esr spectrum of 2-trifluoromethylnitrobenzene anion indicating hindered rotation of the trifluoromethyl group. While it is possible that 2-*t*-butylnitrobenzene anion is similar in a dynamic sense, the question cannot be settled on the basis of the esr spectrum.

We feel that it is significant to note that  $R$  for the *o*-ethylnitrobenzene anion, 0.56, is substantially smaller than  $R$  for the *para* substituent, 0.74–0.80, which is in turn smaller than  $R$  for the nitroethane anion radical,

(55) E. G. Janzen and J. L. Gerlock, *J. Org. Chem.*, **32**, 820 (1967), find no splittings for the bridgehead protons in 2-nitrotricyclic anion radicals. This observation is consistent with eq 2 since  $\theta = 90^\circ$ .

(56) Figure 3 in ref 35 was used for this estimate. The reduced moments of inertia for nitroaromatic and nitroaliphatic anion radicals are sufficiently comparable that this procedure is valid.

(57) We assume that eq 3 is applicable.

(58) E. G. Janzen and J. L. Gerlock, Abstracts, 152nd National Meeting of the American Chemical Society, New York, N. Y., Sept. 1966, Abstract 158-V.

(53) W. T. Dixon and R. O. C. Norman, *J. Chem. Soc.*, 4850 (1964).

(54) L. M. Stock and H. Suzuki, *J. Am. Chem. Soc.*, **87**, 3909 (1965).

(Table III). It should be recalled that  $R$  for **2a** (Figure 5) at the limit of large barrier is 0.50. While tempting to utilize the Stone-Maki model to estimate  $V_0 \sim 4$  kcal mole<sup>-1</sup> it is also clear from the absence of  $C_{2v}$  symmetry (*vide infra*) that the approximation of a simple twofold barrier is not applicable; thus a barrier cannot be evaluated quantitatively. The schematic representation of conformation in Figure 6a is consistent with both alkyl proton and nitrogen coupling constants. By comparison with the range of  $R$  values for *p*-propylnitrobenzene anion, 0.44–0.47, the value of 0.5 for *o*-isopropylnitrobenzene anion is also considerably reduced. This value of  $R$  corresponds to  $V_0 = 4$  kcal mole<sup>-1</sup> for conformation **1a** (Figure 5); since the barrier is not strictly twofold, this value can only be regarded as indicative. The schematic representation in Figure 6b combines data for both nitrogen and proton coupling constants. A substantially larger nitrogen coupling constant would be expected if the two isopropyl groups were *cis* to the nitro group (Figure 6c) rather than *trans* (Figure 6b). Therefore, we can infer from the spatial requirements of the two methyl groups that the preferred orientation is to be that shown in Figure 6b.

The question of the conformation of the neutral parent molecules, the 2-alkylnitrobenzenes, has been examined on the basis of spectrophotometric data.<sup>59</sup>

The twist angles for the nitro group inferred for the various substituents were 2-methyl, 34°; 2-ethyl, 40°; 2-isopropyl, 47°; and 2-*t*-butyl, 65°. The abrupt increase in the twist angle for the *t*-butyl derivative was ascribed to the fact that all the other groups have at least one  $\beta$ -hydrogen atom which permits a favorable orientation such as Figure 6b.

**Electrochemistry.** ESR data provide an understanding of the structure of the anion radical. By contrast standard electrode potentials as approximated by half-wave potentials are dependent on the free-energy difference between the neutral molecule and the anion. The change in half-wave potential attributable to steric effects,  $\Delta E_s$ ,<sup>6</sup> for the *o*-alkylnitrobenzene as computed from data in Table I are 0.06, 0.05, 0.09, and 0.16 v,<sup>60</sup> for methyl, ethyl, isopropyl, and *t*-butyl, respectively. The abrupt effect of the *t*-butyl groups on  $\Delta E_s$  parallels the change of  $a_N$  with alkyl substitution.

**Acknowledgment.** The authors acknowledge support from the National Science Foundation through Grants GP-1985 and GP-4906 as well as through GP-1687 for partial support for purchase of the ESR spectrometer. We are indebted to Professor B. M. Wepster for a gift of 2-isopropylnitrobenzene.

(59) B. M. Wepster, *Progr. Stereochem.*, **2**, 110 (1950).

(60) Since  $E_{1/2}$  for 4-*t*-butylnitrobenzene is not available, a value of 1.19 v vs. sce was assumed in the calculation of  $\Delta E_s$ .

## Absorption and Emission Spectra of 1,2,4,5-Tetracyanobenzene-Naphthalene Complex Crystal

Suehiro Iwata, Jiro Tanaka, and Saburo Nagakura

*Contribution from the Institute for Solid State Physics, University of Tokyo, Azabu-shinryudo-cho, Minato-ku, Tokyo. Received December 30, 1966*

**Abstract:** The electronic absorption and emission spectra of the charge-transfer complex of 1,2,4,5-tetracyanobenzene with naphthalene were studied by measuring them under various conditions, and by carrying out a theoretical study on the basis of configuration interaction among the ground, locally excited, and charge-transfer configurations. By combining the theoretical results with the polarized absorption measurements of the single crystal, it is concluded that the longest wavelength band at 24,600 cm<sup>-1</sup> may be ascribed to the first charge-transfer transition, and that the second charge-transfer band appears at 31,500 cm<sup>-1</sup> overlapping with local excitation bands. The fluorescence spectrum of the crystal at liquid N<sub>2</sub> temperature, which commences at 23,200 cm<sup>-1</sup> and shows vibrational structure, nicely satisfies the well-known mirror image relation to the first charge-transfer band. On the other hand, the fluorescence spectrum of the crystal at room temperature is structureless and is shifted to lower frequencies compared with that at liquid N<sub>2</sub> temperature. The phosphorescence spectrum of the complex observed at liquid He temperature shows well-resolved vibrational structure which is satisfactorily coincident with that of the phosphorescence spectrum of naphthalene itself. This means that the phosphorescent state of the complex may be regarded as the locally (within naphthalene) excited triplet state.

The electronic spectra of charge-transfer (abbreviated hereafter to CT) complexes in crystalline state are interesting research subjects in connection with the theory developed by Mulliken.<sup>1</sup> The experimental evidence for the existence of the CT absorption can be obtained from the directions of the transition moments of the bands determined by polarized absorption measurements of single crystals, and the study of absorption and emission spectra of CT complexes may give valuable

information about the interaction between the CT and locally excited structures and about electron- and energy-transfer phenomena in CT complex crystals. So far, however, the measurements of polarized absorption spectra have been carried out with rather few CT complex crystals, although many studies have been done with electronic spectra of solutions.<sup>2,3</sup> The most

Figure 1. The orbital symmetries of the naphthalene and TCNB molecules and the differences of the orbital energies.  $\epsilon(\theta_2) - \epsilon(\theta_1)$  and  $\epsilon(\phi_2) - \epsilon(\phi_1)$  are estimated by the multi-CT bands.  $\epsilon(\phi_2) - \epsilon(\theta_2)$  is the difference between the ionization potential ( $I_p$ ) of donor and the electron affinity ( $A_f$ ) of acceptor. According to the photoionization experiment (F. I. Vilisov, *Soviet Phys. Usp.* (Engl. Transl.), 6, 888 (1964); *Usp. Fiz. Nauk*, 81, 669 (1963)),  $I_p$  is 8.13 eV.  $A_f$  was estimated to be 1.60 eV by the aid of the CT band positions of some complexes in the previous paper.<sup>8</sup>

extensive studies on the polarized absorption and fluorescence spectra of single crystals have been done for the trinitrobenzene-anthracene complex.<sup>4-7</sup> Hochstrasser and his co-workers observed the vibrational structure in the CT band at room and liquid N<sub>2</sub> temperatures,<sup>4</sup> and they inferred the existence of localized excitons from experimental results showing that the absorption and fluorescence polarization ratios at 300°K are very different from each other.<sup>5</sup> Further, they reported that the CT transition intensity in the crystal is about twice that in solution.<sup>6</sup>

In a previous paper<sup>8</sup> we reported on the absorption spectra of the 1,2,4,5-tetracyanobenzene (TCNB)-mesitylene complex crystal and showed that the absorption band of the acceptor (TCNB) is changed in the complex as a result of the mixing of the CT structure with the TCNB locally excited electronic structure.

The present paper is concerned with the absorption, fluorescence, and phosphorescence spectra of the TCNB-naphthalene complex crystal. We measured the spectra at various temperatures and considered them theoretically by the semiempirical MO method, using the crystal structure of the complex recently determined by Kumakura, Iwasaki, and Saito.<sup>9</sup>

## Experimental Section

TCNB was prepared by Ishitani and Maruyama of our laboratory by the method described in the previous paper.<sup>8</sup> Naphthalene was purified by repeated recrystallizations in ethanol. The TCNB-naphthalene complex crystal was prepared by mixing the acceptor and the donor in methylene chloride and by evaporating the solvent at room temperature.

(8) S. Iwata, J. Tanaka, and S. Nagakura, *J. Am. Chem. Soc.*, 88, 894 (1966).

(9) S. Kumakura, F. F. Iwasaki, and Y. Saito, *Bull. Chem. Soc. Japan*, in press.

The absorption spectra in solution and in thin film were measured with a Cary recording spectrophotometer, Model 14 M. A spectrophotometer attached with a microscope and a Roschen-type polarizer<sup>10</sup> was used for the polarized ultraviolet absorption measurement of single crystals. The emission spectra at room and liquid N<sub>2</sub> temperatures were measured with a JASCO Model CT-50 grating monochromator with a RCA 1P28 or EMI 9529 A photomultiplier tube as detector, and those at liquid H<sub>2</sub> and liquid He temperatures with a Fuess prism monochromator, Kodak 103a F plates being used.

## Theoretical Section

In the previous paper<sup>8</sup> we calculated the electronic structures of the TCNB complexes with methyl-substituted benzenes. Consequently we could predict some possible stable geometrical structures of the complexes.<sup>11</sup> Furthermore, it was demonstrated that the mixing of the CT configuration with the acceptor locally excited configurations plays an important role in the excited states of some CT complexes. A similar theoretical consideration has been made for the TCNB-naphthalene complex on the basis of the structure determined by the X-ray crystal analysis technique.

For the sake of simplicity, only the highest two occupied ( $\phi_1$ ,  $\phi_2$  and  $\theta_1$ ,  $\theta_2$ ) and lowest two vacant molecular orbitals ( $\phi_3$ ,  $\phi_4$  and  $\theta_3$ ,  $\theta_4$ ) of TCNB and naphthalene<sup>12</sup> were considered. The symmetry and energy of each orbital are shown in Figure 1. The wave function of the ground configuration is given by the Slater-type determinant

$$\Phi_G = |\phi_1 \bar{\phi}_1 \phi_2 \bar{\phi}_2 \theta_1 \bar{\theta}_1 \theta_2 \bar{\theta}_2| \quad (1)$$

The lowest CT configurations are

$$\begin{aligned} \Phi_{CT_1} &= \Phi(\theta_2^{-1} \phi_3) \\ \Phi_{CT_2} &= \Phi(\theta_1^{-1} \phi_3) \\ \Phi_{CT_3} &= \Phi(\theta_2^{-1} \phi_4) \\ \Phi_{CT_4} &= \Phi(\theta_1^{-1} \phi_4) \end{aligned} \quad (2)$$

The lowest two locally excited configurations of TCNB and of naphthalene are approximately written as<sup>13</sup> for TCNB

$$\begin{aligned} \Phi_{L1} &= 0.7878\Phi(\phi_1^{-1} \phi_3) + 0.6159\Phi(\phi_2^{-1} \phi_3) \\ \Phi_{L2} &= -0.5032\Phi(\phi_1^{-1} \phi_4) + 0.8642\Phi(\phi_2^{-1} \phi_4) \end{aligned} \quad (3)$$

for naphthalene

$$\begin{aligned} \Phi_{L3} &= \frac{1}{\sqrt{2}} \{ \Phi(\theta_1^{-1} \theta_3) + \Phi(\theta_2^{-1} \theta_3) \} \\ \Phi_{L4} &= \Phi(\theta_2^{-1} \theta_4) \end{aligned} \quad (4)$$

where

$$\Phi(\theta_i^{-1} \phi_j) = \frac{1}{\sqrt{2}} \{ | \dots \theta_i \bar{\phi}_j \dots | + | \dots \phi_j \bar{\theta}_i \dots | \}$$

(10) J. Tanaka, *ibid.*, 36, 833 (1963).

(11) Recently Niimura, Ohhashi, and Saito determined the structure of the hexamethylbenzene (HMB)-TCNB complex by the aid of the X-ray crystal analysis technique.<sup>12</sup> The results are in good agreement with our expectation on the stable configuration. The center of HMB molecule is located above one of the C-C bonds of the TCNB benzene ring.

(12) N. Niimura, Y. Ohhashi, and Y. Saito, General Symposium on Molecular Structure and Spectroscopy, Osaka, Japan, Oct 1966.

(13) The self-consistent field molecular orbitals of TCNB and naphthalene are determined using the Pariser-Parr-Pople approximations. The parameters used for TCNB were described in the previous paper,<sup>8</sup> and Pariser's parameters<sup>14</sup> were used for naphthalene.

(14) R. Pariser, *J. Chem. Phys.*, 24, 250 (1956).

(15) The wave functions of the locally excited configurations were determined by the configuration interaction including the one-electron excited configurations which are composed of the four orbitals considered.

ie configuration interaction among the above nine ron configurations was considered. The energies ie excited configurations  $\Phi_{L1}$ ,  $\Phi_{L2}$ ,  $\Phi_{L3}$ , and  $\Phi_{L4}$  are 1 to be equal to the corresponding transition ener- observed with TCNB and naphthalene, the energy ie ground configuration  $\Phi_G$  being taken to be the ard:  $E_G = 0$ ,  $E_{L1} = 3.93$ ,  $E_{L2} = 4.66$ ,  $E_{L3} = 4.06$ ,  $E_{L4} = 4.43$ . The energies of the CT configurations, the configuration being taken as an example, can be ated as

$$\cong +\epsilon(\phi_3) - \epsilon(\theta_2) - \int \phi_3(1)\phi_3(1)\frac{e^2}{r_{12}}\theta_2(2)\theta_2(2) \times d\tau_1 d\tau_2 = I(\theta_2) - A(\phi_3) - C_{23} \quad (5)$$

ie  $\epsilon(\phi_3)$  and  $\epsilon(\theta_2)$  are the orbital energies, and  $I(\theta_2)$   $A(\phi_3)$  are the ionization potential of the donor and electron affinity of the acceptor, respectively (see re 1).  $C_{23}$  is the Coulomb repulsion energy ben two electrons belonging to  $\phi_3$  and  $\theta_2$  orbitals. ct, it is evaluated with the aid of the point-charge oximation. In the above expressions for the guration energies the following two approxima- are adopted. (1) The electrostatic interaction gies between the two component molecules are equal ie ground and locally excited configurations, be- both the donor and acceptor molecules have no le moment and so the electrostatic interaction is ght to be very small. (2) The overlap integrals een the donor and acceptor orbitals are neglected. ing the SCF MO of the isolated constituent mole- , we can write the off-diagonal elements of the electron Hamiltonian which represent the inter- n of the ground configuration with the excited gurations as<sup>16</sup>

$$H|\Phi(\theta_i^{-1}\phi_{j'})\rangle - \langle\Phi_G|\Phi(\theta_i^{-1}\phi_{j'})\rangle E_0 = \bar{2}\left[\left(i|-\frac{1}{2}\Delta + V(A) + V(D_i^+)|j'\right) - S_{ij'}\{\epsilon_i + \sum_{k'} S_{ik'}(k'|V(D_i^+)|j') - \sum_k S_{kj}(k|V(A)|i)\right] \quad (6)$$

ie operators  $V(A)$ ,  $V(D)$ , and  $V(D_i^+)$  are defined

$$V(D)|\varphi_i\rangle = -\sum_d \int \varphi_j^*(1)\varphi_k(1)\frac{Z_d}{r_{d1}}\varphi_i(1)d\tau_1 + \sum_k \{2(\varphi_j\varphi_i|kk) - (\varphi_j k|k\varphi_i)\} V(D_i^+)|\varphi_i\rangle = (\varphi_j|V(D)|\varphi_i) - (\varphi_j\varphi_i|ii) + (\varphi_j i|i\varphi_i)$$

$$\varphi_j\varphi_i|\varphi_k\varphi_i\rangle = \int \varphi_j^*(1)\varphi_k^*(2)\frac{1}{r_{12}}\varphi_k(1)\varphi_i(2)d\tau_1 d\tau_2$$

1 6, the terms higher than second order with regard are neglected. The first and second terms of this tion contribute mainly to the value of the integral. third and fourth terms are thought to be small pared with the first and second terms and may be

The matrix elements in the variation method including the over- egrals are  $\mathcal{K} - S\epsilon$ . As we take the energy  $E_0$  of the ground on- ion as standard,

$$\mathcal{K} - S\epsilon = (\mathcal{K} - SE_0) - SE$$

—  $S_{12}E_0$  is the off-diagonal element considered.

J. N. Murrell, *J. Am. Chem. Soc.*, **81**, 5037 (1959).

neglected. Nonempirical evaluations of the terms in eq 6 are so difficult that we evaluate them semiempir- ically

$$\langle\Phi_G|H|\Phi(\theta_i^{-1}\phi_{j'})\rangle - \langle\Phi_G|\Phi(\theta_i^{-1}\phi_{j'})\rangle E_0 = \sqrt{2}(-KS_{ij'}) \quad (6')$$

The other important type of the off-diagonal elements are those between the CT and locally excited con- figurations (eq 7). The semiempirical parameters  $K$

$$\langle\Phi(\theta_i^{-1}\phi_{j'})|H|\Phi(\phi_{i'}^{-1}\phi_{j'})\rangle - \langle\Phi(\theta_i^{-1}\phi_{j'})|\Phi(\phi_{i'}^{-1}\phi_{j'})\rangle E_0 = -\left(i'|-\frac{1}{2}\Delta + V(D_i^+) + V(A)|i\right) - (j'j'|i'i) + 2(j'i|i'j') - S_{ii'}(+\epsilon_{j'} - \epsilon_i - \epsilon_{i'} - J_{ii} - J_{i'i'}) + S_{ij'}(i'|V(D_i^+)|j') + \sum S_{ik'}\{(i'|V(D_i^+)|k') + (j'j'|i'k') - (j'k'|i'j')\} + \sum S_{i'k'}\{(i|V(A_{i'}^+)|k) + (j'j'|ik) - (j'k'|ij')\} \simeq -K'S_{ii'} \quad (7)$$

and  $K'$  in eq 6' and 7 are not exactly the same, but we set both  $K \simeq 10$ .<sup>8</sup> For calculating the overlap inte- grals, Roothaan's expanded Hartree-Fock atomic orbital functions<sup>18</sup> were used.

The interaction between the locally excited con- figurations of different molecules can be expressed as

$$\langle\Phi(\theta_i^{-1}\theta_j)|H|\Phi(\phi_{i'}^{-1}\phi_{j'})\rangle - \langle\Phi(\theta_i^{-1}\theta_j)|\Phi(\phi_{i'}^{-1}\phi_{j'})\rangle E_0 = 2(ji|j'i') - (jj'|i'i) - S_{jj'}\left(i|-\frac{1}{2}\Delta + V(A) + V(D)|i'\right) - S_{ii'}\left(j|-\frac{1}{2}\Delta + V(A) + V(D)|j'\right) \simeq 2(ji|j'i') \quad (8)$$

The off-diagonal term between two CT configurations can be expressed by the equation similar to the above. This is the interaction energy between two transition charge densities. For the interaction between the two CT configurations, the interaction energy was calcu- lated by the point-charge approximation. On the other hand, the interaction energy between the two locally excited configurations was estimated by using the experimental transition dipoles because the wave functions of the locally excited configurations in which only the four orbitals are included are not good enough to give agreement between the calculated transition moments and the observed values. Also, the transition charge density of the lowest excited state  $\Phi_{L3}$  of naphtha- lene is zero within LCAO-MO approximation.

## Results and Discussion

**The Structure of the Naphthalene-TCNB Complex.** In a structure where the center of a donor molecule is located just above that of the acceptor and the long axis of one molecule is parallel to that of the other, the lowest CT configuration,  $\Phi(\theta_2^{-1}\phi_3)$ , can mix with the ground configuration because the orbitals  $\theta_2$  and  $\phi_3$  have same symmetry. The stabilization energy  $\Delta E$  due to CT interaction was evaluated for this model and for two series of the geometrical models.

First, we allow one molecule to rotate around the axis perpendicular to molecular plane fixing the centers of the molecules. All four CT configurations under

(18) E. Clementi, "Tables of Atomic Functions," a supplement to the paper which appears in IBM J. Res. Develop., **9**, 2 (1965).

Figure 2. The potential curves calculated for the ground and lowest CT excited states. When  $R_x = 0$ , the center of TCNB molecule is located just above that of the naphthalene molecule. When  $R_x = 1.2$  Å, there is the benzene ring of TCNB just over one benzene ring of naphthalene.

consideration stabilize the ground state, and the calculated stabilization energy is little dependent on the rotation angle  $\theta$ ; for example, when  $\theta = 0^\circ$ ,  $\Delta E = -0.09$  eV, and, when  $\theta = 90^\circ$ ,  $\Delta E = -0.08$  eV. On the other hand, in these structures the lowest four locally excited configurations of the donor and acceptor and the four CT ones do not interact at all because of the symmetry of the orbitals.

Next, we try to shift one molecule along the  $x$  direction which is parallel to the long axis of molecules. The calculated potential curves for the ground and lowest excited states are shown in Figure 2. This time the stabilization energy changes from  $-0.09$  to  $-0.01$  eV with increasing  $R_x$  from 0 to 1.20 Å, where  $R_x$  is the  $x$  coordinate of the center of one molecule when the origin is taken to be the center of the other. When  $R_x \neq 0$ , the interaction between the lowest CT configuration and the lowest excited configuration within the donor and acceptor occurs, so that the lowest CT excited state is lowered from 3.32 to 3.17 eV with changing  $R_x$  from 0 to 1.20 Å. A similar result was obtained when one molecule is shifted along the short axis of the other molecule.

Thus the theoretical results seem to show that the stable structure in the ground state may be the structure in which the center of one molecule is located just above that of the other.

The crystal structure of TCNB-naphthalene complex has been determined by Kumakura, Iwasaki, and Saito.<sup>9,10</sup> According to their results, the donor and acceptor molecules are stacked alternately in columns parallel to the  $c$  axis, and their planes are nearly perpendicular to this axis. Figures 3a and b show projections of TCNB and naphthalene molecules onto the plane perpendicular to the  $c$  axis and the  $\{110\}$  face of the complex crystal, respectively. According to Figure 3a the center of one molecule is just above that of the other molecule, and the long axis of naphthalene molecules in the complex is at an angle of  $\theta$  ( $\theta$  is about  $20^\circ$ )

(19) The crystal is monoclinic and the space group is  $C2/m$ , with the two complexes in a unit cell. The complex crystallizes as needles, with the long axis parallel to  $c$ . The centers of TCNB molecules occupy  $(0, 0, 0)$  and  $(\frac{1}{2}, \frac{1}{2}, 0)$  positions in a unit cell, while those of naphthalene molecules are placed in  $(0, 0, \frac{1}{2})$  and  $(\frac{1}{2}, \frac{1}{2}, \frac{1}{2})$  positions.

Figure 3. (a) Projection onto a plane perpendicular to the  $c$  axis. (b) Projection onto the  $\{110\}$  face, in which the absorption measurements were made.

with respect to the  $a'$  axis which is parallel to the long axis of TCNB molecule.<sup>20</sup>

Thus the structure in crystal is coincident with our theoretical expectation. From this it may be inferred that the stacking of the molecules in this crystal may be mainly controlled by the CT force.<sup>21</sup> On the basis of the structure determined by the X-ray crystal analysis technique, the energy levels and wave functions of the ground and excited states of the complex have been calculated by the method described in the Theoretical Section. The results are given in Table I.

**The Crystal Absorption Spectra.** The visible and near-ultraviolet absorption spectra of the single crystal measured at room temperature are shown in Figure 4a. They have two peaks polarized parallel to the  $c$  axis and one peak polarized perpendicular to it. By comparing them with the solution spectra of TCNB, naphthalene, and the TCNB-naphthalene complex shown in Figure 4b, it is concluded that the first band at  $25,000\text{ cm}^{-1}$  in crystal and in solution can be regarded as the CT band. The absorption intensity

(20) The angle may be either  $+\theta$  or  $-\theta$ . This disorder does not affect the discussion on the polarization of the CT bands, but the polarization of the intramolecular local excitations of naphthalene in the  $\{110\}$  face should be carefully discussed, because both short and long axes of naphthalene molecules are projected onto the  $\{110\}$  face at different angles between molecules with an angle of  $+\theta$  and  $-\theta$ .

(21) In some CT complex crystal, the steric factor, a methyl group, plays an important role in the way of stacking. The TCNB-TMPD complex is a case in point.<sup>22</sup> On the other hand, in HMB-TCNB complexes, molecules are so nicely stacked that the CT force is strong (see ref 11).

The theoretical consideration has been made with the complex with geometrical orientation in crystal. The ground and lowest four CT configurations are little mixed with the TCNB and naphthalene locally excited configurations because of the molecular orbital symmetry.

io ( $A_{\parallel}/A_{\perp}$ ) for light polarized parallel and perpendicular to the  $c$  axis is far larger than 25:1.

According to the X-ray crystal analysis data, TCNB and naphthalene molecules are stacked alternately in columns parallel to the  $c$  axis, and the centers of the molecules are on the  $c$  axis. Therefore we can safely say that the direction of the transition moment of the first CT band at 25,000  $\text{cm}^{-1}$  is nearly parallel to the line connecting the centers of the two component molecules. This fact supports the interpretation of this band as the first CT band.

The second band in the  $\sim 33,000$ – $29,000$ - $\text{cm}^{-1}$  region is also polarized parallel to the  $c$  axis. This means that this band can be assigned to a CT transition as well. From the theoretical point of view, the appearance of two CT bands in the  $\sim 25,000$ – $35,000$ - $\text{cm}^{-1}$  region is quite reasonable.

From the calculated energy levels given in Table I, the transition energies  $W_i - W_0$  can be evaluated and are given in the same table. The results show that five absorption bands corresponding to the  $W_0 \rightarrow W_i$  ( $i = 1-5$ ) transitions appear in the  $\sim 25,000$ – $38,000$ - $\text{cm}^{-1}$  region. From the wave functions given in Table I, it is revealed that the  $W_0 \rightarrow W_1$ ,  $W_0 \rightarrow W_2$ , and  $W_0 \rightarrow W_3$  transitions are of CT character, and the  $W_0 \rightarrow W_4$  and  $W_0 \rightarrow W_5$  transitions are of local excitation. The first CT band at 25,000  $\text{cm}^{-1}$  clearly corresponds to the  $W_0 \rightarrow W_1$  transition and is due to the transition from the highest occupied orbital ( $\theta_2$ ) of naphthalene to the lowest vacant orbital ( $\phi_3$ ) of TCNB. There are two possibilities for the interpretation of the second CT band. One of them is the transition from the second highest occupied ( $\theta_1$ ) orbital of naphthalene to the lowest vacant orbital ( $\phi_3$ ) of TCNB, and the other is the transition from the highest occupied orbital ( $\theta_2$ ) of naphthalene to the second lowest vacant orbital ( $\phi_4$ ) of TCNB (see Figure 1). The separation of  $\Delta\nu_{CT}$  between the first and second CT bands may be expected to be 5200  $\text{cm}^{-1}$  in the former case from the corresponding values for naphthalene complexes containing tetracyanoethylene (TCNE) and chloranil as electron acceptor.<sup>2</sup> On the other hand, the  $\Delta\nu_{CT}$  value for the latter case was calculated by us<sup>8</sup> to be 6300  $\text{cm}^{-1}$  from the analysis of the absorption spectra of various TCNB complexes with substituted benzenes. The tentative  $\Delta\nu_{CT}$  values for the two cases are rather close to each other, and either of

them can explain the observed position of the second CT band. Therefore, the observed second CT band may be due to both the above-mentioned transitions. The observed absorption intensity ratio of the first CT band to the second is about 1:0.88, while the calculated transition probability ratio of the first transition to the second plus the third one is 1:0.68.

Figure 4a. The absorption spectra of the single crystal of the complex in the {110} face at room temperature. The ordinate is the absorbance in arbitrary units.

There appears in the 33,000–29,000- $\text{cm}^{-1}$  region another band which is polarized almost perpendicular to the  $c$  axis. From the direction of the transition moment, this band may be regarded as due to the intramolecular local excitations of the respective component molecules. In fact, the TCNB and naphthalene molecules show absorption bands with vibrational structures in this region as is shown in Figure 4b.<sup>23</sup> As the absorption intensity of TCNB local excitation is larger by about 10 times than that of naphthalene, the observed band at 31,000  $\text{cm}^{-1}$  perpendicular to the  $c$  axis is assigned to the TCNB local excitation. In the crystal,

(23) The first absorption band of the TCNB crystal which was observed in the previous paper<sup>8</sup> is little perturbed by crystal field, and its position and vibrational structure are very similar to those of the solution spectrum. On the other hand, the absorption spectrum of the naphthalene crystal is known to be different from the spectrum in solution. In our case we should compare the absorption of naphthalene in the complex with that in solution or in solid mixed solution.

Figure 4b. The absorption spectra of naphthalene (.....) and TCNB (----) in  $\text{CH}_2\text{Cl}_2$ . The absorption spectrum of the  $\text{CH}_2\text{Cl}_2$  solution containing naphthalene (0.065  $M$ ) and TCNB (0.0009  $M$ ) (—), the absorption intensity of which is shown in arbitrary units.

Figure 5. The absorption spectra of the thin film of the complex and TCNB only on a quartz plate. The ordinate is the absorbance in arbitrary unit: —, complex at 88°K; ----, complex at 298°K; —, TCNB only at 88°K.

the vibrational structure is blurred and the spectrum becomes broad as a whole. The reason for this is discussed in a later part of the present paper by taking into consideration the observed absorption spectra at low temperature.

In connection with the interpretation of the absorption spectrum of the CT complex, it seems to be interesting to measure it at low temperature. It is difficult, however, to do this with the single crystal principally because of technical difficulties. We prepared the thin film of the TCNB complex with naphthalene on a quartz plate and measured its absorption spectrum at 88°K.<sup>24</sup> The results are shown in Figure 5.<sup>25</sup> At 88°K vibrational structures in the first CT band appear

(24) We are indebted to Mr. T. Sakata for this method of absorption measurement at low temperature. He and the present authors have checked the reliability of this method with various samples. This method is known to give the results similar to those obtained by refraction method or by microscopic method with single crystals.

(25) The absorption intensity ratio of the 32,000- $\text{cm}^{-1}$  bands to the 25,000- $\text{cm}^{-1}$  band is about 2.1:1 in the spectra measured with the thin film of the CT complex, while the corresponding value for the single crystal is about 1.3:1. These results do not conflict with each other, because in the single crystal the CT band at 25,000  $\text{cm}^{-1}$  was observed in the direction of  $c$  axis under the most optimal conditions, but the transition moments of the local excitation bands at 32,000  $\text{cm}^{-1}$  with the polarization in the long axis of the component molecules are projected on the perpendicular direction to the  $c$  axis in the  $\{110\}$  plane with an angle  $\varphi$  ( $\varphi = \tan^{-1} b/a'$ )  $\approx 55^\circ 40'$ .

Figure 6. The absorption and fluorescence spectra of the complex: (1 and 2) the absorption spectra of the thin film on a quartz plate at 113 and 298°K, respectively (the ordinate is the absorbance in arbitrary unit); (3 and 4) the fluorescence spectra of the microcrystal at 77 and 298°K, respectively (the ordinate is the emission intensity); (5) the fluorescence spectra of the thin film at 298°K (see ref 28).

clearly at 24,300, 25,600, and 26,800  $\text{cm}^{-1}$ , while the tail extending to the longer wavelength region of the first band at room temperature disappears. This seems to mean that the transition bands from thermally excited vibrational states of the ground state, the so-called hot bands, provide the explanation of the tail in the longer wavelength side of the first CT band.

The absorption bands of the complex in the shorter wavelength region, which are broad at room temperature, become a little sharp at 88°K and exhibit three indistinct peaks at 30,600, 31,800, and 32,700  $\text{cm}^{-1}$  (see Figure 5). We also measured the absorption spectrum of TCNB itself under the same conditions. The result is shown in Figure 5 for the purpose of comparison. As is clearly seen in Figure 5, the vibrational structure of the latter is much more distinct than that of the former. From the above-mentioned facts, it might be inferred that the absorption spectrum of the complex at room temperature becomes broad for the following two reasons: first, because of the presence of hot bands due to the shallowness of the ground-state potential energy curve; second, because of the interaction of the locally excited configuration of TCNB with some high-energy configurations which were not considered in our theoretical study.<sup>26</sup>

**Fluorescence Spectra of Complex Crystal.** The fluorescence spectra of the complex crystal at room and liquid  $\text{N}_2$  temperatures are shown in Figure 6, together with the absorption spectra. The fluorescence spectra at liquid  $\text{H}_2$  and liquid  $\text{He}$  temperatures are the same as at liquid  $\text{N}_2$  temperature. A good mirror image relation between the fluorescence spectrum and the CT absorption spectrum is found at liquid  $\text{N}_2$  temperature, so that the fluorescent state is concluded to be the lowest CT state. The overlap between the fluorescence and absorption spectra in the 23,200- $\text{cm}^{-1}$  region is very small. This suggests that the geometric structure of the fluorescent state may be different from that of the ground state of the complex.

(26) Because of the relative orientation of donor and acceptor molecules in crystal and the symmetry of the excited states, both local excitations considered are little mixed with the lowest four CT configurations, and the interactions between the donor and acceptor local excitations may be small in view of the low transition intensities.

the case of the naphthalene-TCNB complex crystal. The Franck-Condon principle leads to the conclusion that the absorption intensity of the CT transition is high when both the ground state and the CT excited state are coupled with neither intramolecular nor intermolecular vibrations. Therefore the excited state corresponding to the longest wavelength absorption at  $24,300\text{ cm}^{-1}$  seems to be coupled with some molecular vibrations. The similar consideration can be applied to the fluorescence.

At room temperature the mirror image relation between the absorption spectrum and the fluorescence spectrum of the microcrystal is not satisfied. One of the reasons for this may be the reabsorption corresponding to the long tail which was interpreted as the band. Another reason is that the fluorescence at room temperature may be a type of "excimer emission" in the perylene  $\beta$  crystal.<sup>27</sup> The formation of the "excited complex" might be possible at room temperature. The excited molecule is displaced over to the more stable structure, which may be aided by the interactions between the CT and localized electronic configurations.<sup>28,29</sup>

**Phosphorescence Spectra of the CT Complex in a Crystal.** A phosphorescence was observed with the complex of the naphthalene-TCNB complex at low temperature. Figure 7 shows the phosphorescence spectra at liquid  $\text{N}_2$  and liquid He temperatures, which are very different from each other. The spectra at liquid He temperature show the line structure with the background in the low-frequency region. The maxima of the line spectra are given in Table II together with those of the phosphorescence spectrum of naphthalene in the heptane and pentane matrix. The two spectra correspond well to each other. The  $\text{D}_0$  band position and in vibrational structure. Therefore it is concluded that the phosphorescent state in the crystal is the naphthalene locally excited triplet state. Extra fine structure, thought to be due to the lattice vibrations, was observed for the crystal of the complex. The observation of lattice vibrations in the phosphorescence spectra may suggest that the emitting

naphthalene is combined with the acceptor TCNB in the ground state and is not the extra naphthalene in crystal.

Tanaka, *Bull. Chem. Soc. Japan*, **36**, 1237 (1963).

For the sake of the elimination of the reabsorption, the emission of a thin layer of powder was observed. But at room temperature, emission of powder, which is made by crushing the crystal using mortar, appears in longer wavelengths than that of the microcrystal is shown in Figure 6. At liquid  $\text{N}_2$  temperature, however, emission of this powder is in agreement with that of the microcrystal. The usual phenomenon of powder emission cannot be simply explained although perhaps it may be related to the energy transfer to the traps. We could not obtain at room temperature the fluorescence spectra of crystal in which the reabsorption effects were eliminated.

In solution we found the "excimer" type of fluorescence for some complexes. In TCNB-benzene, -toluene, and -mesitylene the fluorescence spectra at room temperature appear in the very long wavelength region. At liquid  $\text{N}_2$  temperature they have the mirror image relation with the absorption spectra. We will discuss the phenomena in more detail in a future publication.

The spectra at liquid  $\text{N}_2$  and  $\text{H}_2$  temperatures are composed of broad bands, which appear in the same wavelength regions as those at liquid He temperature. Therefore the phosphorescence state at liquid  $\text{N}_2$  and  $\text{H}_2$  temperatures may also be related to the naphthalene triplet state, which is perturbed by the CT interaction. It is a problem why the complex crystal can emit the long-lived phosphorescence and why the temperature dependence of phosphorescence occurs. The most probable reason is that the emitting complexes are a type of traps in crystal.

**Acknowledgment.** The authors express their sincere thanks to Professor Y. Saito, Dr. F. F. Iwasaki, and Mr. S. Kumakura of our institute for their kindness in informing us of their X-ray analysis data on the TCNB-naphthalene complex prior to the publication.

# Conformational Changes Involved in the Singlet-Triplet Transitions of Biphenyl<sup>1</sup>

Peter J. Wagner

Contribution from the Department of Chemistry, Michigan State University, East Lansing, Michigan. Received November 4, 1966

**Abstract:** The lowest energy band in the  $T^* \leftarrow S$  absorption spectrum of biphenyl in benzene solution appears at 75.5 kcal. Naphthalene and conjugated dienes are 2.5 times more effective than biphenyl at quenching triplet butyrophenone and at least 20 times more effective than biphenyl at quenching triplet benzophenone. The actual quenching efficiency of biphenyl decreases with increasing benzophenone concentration because of reversible energy transfer. From these absorption and quenching data, plus phosphorescence data in the literature, it is concluded that neither the highest energy band in the phosphorescence spectrum at 65.5 kcal nor the lowest energy band in the solution  $T^* \leftarrow S$  absorption spectrum at 75.5 kcal represents the true  $T^* \leftrightarrow S$  0-0 transition of biphenyl, which occurs around 69.5 kcal and is a nonspectroscopic transition between a twisted ground state and a triplet state of grossly different geometry. Evidence that triplet biphenyl prefers to be planar is presented and discussed.

In recent measurements of the phosphorescence spectrum of biphenyl in frozen glasses, the highest energy band has been located at 65.5 kcal and assigned as the  $T^* \rightarrow S$  0-0 transition.<sup>2</sup> If the actual energy difference between the lowest vibrational levels of the ground and first triplet states were 65.5 kcal, biphenyl ought to quench higher energy (>68 kcal) ketone triplets at close to the diffusion-controlled rate in solution.<sup>3-5</sup> Since biphenyl absorbs only negligibly at 3130 Å and is not known to undergo any photochemical changes, it seemed that it might be a choice quencher for use in studies of the triplet-state photochemistry of ketones. The work to be described grew out of a test of this assumption.

## Results

**Quenching of Butyrophenone Photoelimination.** Biphenyl and several other aromatic and olefinic compounds with low-lying triplet states were used to quench type-II photoelimination of butyrophenone, whereby the excited molecule splits into ethylene and acetophenone. This reaction has been shown to proceed exclusively from the triplet state of the ketone.<sup>6,7</sup> Pyrex tubes containing benzene solutions 0.20 *M* in ketone, 0.005 *M* in *n*-tetradecane as internal standard, and containing various concentrations of the different quenchers were degassed, sealed *in vacuo*, and irradiated in parallel such that each sample absorbed the same intensity of 3130- or 3660-Å radiation. The amount of acetophenone formed in each tube was then determined by glpc analysis. The highest conversion, in samples with no quencher, was 6%. Stern-Volmer plots, such as exemplified in Figure 1, were linear for each quencher,

their slopes yielding the  $k_q\tau$  values listed in Table I. Since the lifetime of triplet butyrophenone,  $\tau$ , is the same regardless of quencher, it is apparent that biphenyl is less efficient a quencher by a factor of 0.40 than are the other compounds studied, all of which are commonly assumed to be "diffusion-controlled" quenchers. The fact that the quenching efficiency of naphthalene appeared slightly higher than that of the others probably is not significant, since acetophenone and naphthalene were not completely separated under the analytical conditions employed, and a small systematic error may readily have been introduced.

Table I. Efficiencies of Various Compounds at Quenching Photoelimination of Butyrophenone

Compound	$E_T^a$	Wavelength, Å	$k_q\tau$ , $M^{-1}$

**Quenching of Propiophenone Photoreduction.** Isopropyl alcohol solutions 0.10 *M* in propiophenone and containing various concentrations (0-0.012 *M*) of naphthalene or biphenyl were degassed and irradiated in parallel in sealed Exax tubes at 3660 Å. The disappearance of propiophenone was monitored by ultraviolet analysis. Again Stern-Volmer plots were linear and yielded slopes equal to 204 and 136  $M^{-1}$  for naphthalene and biphenyl, respectively. Cohen has reported a  $k_q\tau$  value of ~170  $M^{-1}$  for the acetophenone-isopropyl alcohol-naphthalene system.<sup>8</sup>

**Quenching of Benzophenone Photoreduction.** Biphenyl and several other compounds were employed to quench the photoreduction of benzophenone by benz-

The inefficiency of biphenyl at quenching triplet benzophenone is quite dramatic, naphthalene and the diene being some 145 times more effective. The two *ortho*-substituted biphenyls are even less effective than biphenyl itself. Triphenylene and fluorene display higher

energy phosphorescence bands than does biphenyl, and thus might be presumed to possess higher energy triplet states. Nonetheless they are appreciably better quenchers than biphenyl. Actually the quenching behavior of fluorene is somewhat anomalous in that Stern-Volmer plots bend upward. In systems where energy transfer is reversible,<sup>14</sup> self-quenching or quenching by trace impurities could cause this behavior. The value for  $k_q\tau$  recorded in Table II was calculated by extrapolating the slopes of the plot in Figure 2 to zero fluorene concentration.

Sandros<sup>14</sup> has shown that reversible energy transfer is likely when quenching rate constants are several orders of magnitude below that of diffusion. Consequently a brief study was made of the effect of benzophenone concentration on the quenching efficiency of biphenyl. Two series of samples were prepared and analyzed as above, except that somewhat lower concentrations of biphenyl were used and benzophenone concentrations were 0.020 or 0.0050 *M*. Figure 3,

Figure 4. Plot of the reciprocal of the Stern-Volmer slopes in Figure 3 against benzophenone concentration.

which displays Stern-Volmer plots of the results, demonstrates the greater quenching efficiency of biphenyl at lower benzophenone concentrations. The Stern-Volmer slopes are included in Table II.

Straightforward kinetic analysis of reversible energy transfer yields the following modification of the usual Stern-Volmer equation (eq 1). In the system under

$$\frac{\Phi_0}{\Phi} = 1 + \frac{k_q\tau[Q]}{1 + \frac{k_{-q}[K]}{k_d'}} \quad (1)$$

consideration,  $\tau$  represents the lifetime of triplet benzophenone in the presence of 0.20 *M* benzhydrol and no added quencher;  $k_q$ , the rate constant for energy transfer from triplet benzophenone to biphenyl;  $k_{-q}$ , the rate constant for energy transfer from triplet biphenyl to ground-state benzophenone;  $[K]$ , the concentration of benzophenone;  $[Q]$ , the concentration of biphenyl; and  $k_d'$ , the rate of decay of triplet biphenyl.

Equation 1 describes the inverse relationship between the slopes of the Stern-Volmer plots and ketone concentration. Letting  $S$  equal the slope of a given Stern-Volmer plot, the following expression results.

$$\frac{1}{S} = \frac{1}{k_q\tau} \left( 1 + \frac{k_{-q}[K]}{k_d'} \right) \quad (2)$$

Figure 4 depicts the linear adherence of the present results to eq 2. The intercept of 0.0080 yields a value of 125 *M*<sup>-1</sup> for  $k_q\tau$ , and the slope of 0.95 yields a value of 118 *M*<sup>-1</sup> for  $k_{-q}/k_d'$ .

After corrections for reversibility, the rate of energy transfer from triplet benzophenone to biphenyl turns out to be 1/20th the "diffusion-controlled" rate to naphthalene and the diene.

Although no detailed studies were carried out, it is very probable that the  $S$  values for fluorene and for triphenylene also depend on benzophenone concentration, so that the true values of  $k_q\tau$  for them are appreciably greater than those listed in Table II.

**T\* ← S Absorption of Biphenyl.** Since the phosphorescence spectrum of biphenyl does not allow correct

Figure 5. Long-wavelength electronic absorption spectra of biphenyls, all in 5-cm cells: (1) 1.5 *M* biphenyl in benzene vs. benzene; (2) 1.0 *M* biphenyl, 6 *M* methyl iodide in 2,2,4-trimethylpentane vs. 6 *M* methyl iodide in 2,2,4-trimethylpentane; (3) 0.7 *M* *p*-bromobiphenyl in benzene vs. benzene; (4) low-wavelength end of a typical phosphorescence spectrum of biphenyl at 77°K in a glass (ref 21).

prediction of its quenching efficiency, a search for the T\* ← S absorption spectrum of biphenyl was undertaken. A 1.5 *M* benzene solution of biphenyl in a 5-cm cell displays weak, almost featureless absorption beginning around 4200 Å, there being two weak but quite distinct maxima at 3790 Å ( $\epsilon \sim 0.004$ ) and at 3600 Å ( $\epsilon \sim 0.006$ ). Any further structure is masked by intense absorption at wavelengths below 3500 Å. This feeble absorption system is assigned to a spin-forbidden T\* ← S transition for several reasons. Bubbling nitrogen through the cell to remove oxygen decreases the intensity,<sup>15</sup> while inclusion of methyl iodide in the solvent enhances the intensity. Moreover, 4-bromobiphenyl also absorbs more strongly in the same region. No band structure, however weak, could be detected in these presumed heavy atom enhanced<sup>16</sup> T\* ← S transitions. Typical absorption curves, together with a phosphorescence spectrum from the literature, are presented in Figure 5. Kearns, using the phosphorescence excitation technique, has also found almost featureless T\* ← S absorption for biphenyl in exactly the same region reported here.<sup>17</sup>

It is apparent that there is little, if any, overlap between emission and absorption and that there is a 10-kcal difference between the highest energy phosphorescence band at 65.5 kcal and the lowest energy absorption band at 75.5 kcal.

## Discussion

**Spectroscopic Transitions of Biphenyl.** The T\* ↔ S emission and absorption spectra of biphenyl yield estimates of its triplet excitation energy which seem to differ by 10 kcal. This problem of nonoverlapping emission and absorption spectra is not a new one and is a direct result, of course, of the Franck-Condon principle.<sup>18</sup> When the lowest vibrational levels

und and excited states possess significantly different equilibrium geometries, true spectroscopic 0-0 transitions are forbidden, and the divergent apparent bands observed in emission and absorption spectra represent transitions from one vibrationally relaxed state to a vibrationally excited mode of the other state.

In the present case of biphenyl, it would appear that there exists a gross geometric difference between the ground state and the excited triplet state. The highest energy band in the phosphorescence spectrum at 65.5 kcal probably should be reinterpreted as a transition from the triplet state in its equilibrium geometry to a vibrationally or rotationally excited ground state. The rise of the  $T^* \leftarrow S$  absorption band at 75.5 kcal probably represents a transition from vibrationally and rotationally relaxed ground state to a nonequilibrium conformation of the excited triplet. The true 0-0 energy difference must lie somewhere intermediate between 65.5 and 75.5 kcal and represents a *nonspectroscopic* transition which is forbidden in radiative processes but allowed in bimolecular energy-transfer reactions. The long tail out to 4200 Å in the  $T^* \leftarrow S$  absorption spectrum probably can be attributed to excitation by the small percentages of ground-state isomers in nonequilibrium geometries, as will be discussed later.

Any exact interpretation would not be justified by spectroscopic data alone, but it is the only one consistent with the quenching results now to be discussed.

**Triplet-Energy Transfer Involving Biphenyl.** The data in Tables I and II for naphthalene, the stilbenes, and the dienes provide further evidence that the efficiency of triplet-energy transfer in solution is equally low for all compounds whose triplet energies are sufficiently lower than that of the donor. Biphenyl clearly acts as such a "diffusion-controlled" quencher toward three ketones studied. The marked inefficiency of biphenyl which quenches triplet benzophenone indicates that the triplet energy of biphenyl is at least as low as that of the ketone.

From the rate constants for triplet-energy transfer from the three ketones to biphenyl, the rate constant for energy transfer to biphenyl can be estimated. Flash photolysis studies<sup>3,5</sup> have indicated that naphthalene, stilbenes, and conjugated dienes all quench triplets with excitation energies as high as those of the ketones with what seems to be a maximum bimolecular quenching rate constant of  $5 \times 10^9 M^{-1} \text{sec}^{-1}$  in benzene. The rate constant for quenching of triplet butyrophenone ( $E_T \sim 72.5 \text{ kcal}^{19}$ ) by biphenyl is thus calculated as  $2 \times 10^9 M^{-1} \text{sec}^{-1}$ , while that for the quenching of triplet benzophenone ( $E_T = 69.5 \text{ kcal}^{19}$ ) by biphenyl is  $2.5 \times 10^8 M^{-1} \text{sec}^{-1}$ . Quenching rate constants have not been measured in isopropyl alcohol; however, the rate constant for diffusion can be calculated from viscosity<sup>20</sup> as  $4.5 \times 10^9 M^{-1} \text{sec}^{-1}$ . If it is assumed that naphthalene quenches triplet propiophenone ( $E_T = 74 \text{ kcal}^{12}$ ) with this rate constant, that for biphenyl would be  $3 \times 10^9 M^{-1} \text{sec}^{-1}$ . This value is somewhat greater than that estimated for the lower energy butyrophenone, but it is noteworthy that the efficiency of

triplet-energy transfer to biphenyl is measurably less than maximal even in a fairly viscous solvent and with a quite high-energy donor.

The inefficiency in the quenching of triplet butyrophenone by biphenyl is reasonably readily explained. In order for vertical-energy transfer to take place, in which process the geometry of the biphenyl remains constant, a donor with at least a 75.5-kcal triplet energy is required. However, as will be discussed below, the vibrationally relaxed triplet of biphenyl, of a geometry substantially different from that of the ground state, lies no more than 70 kcal above the ground state. Consequently, energy transfer to biphenyl involves *nonvertical* transitions in which the geometry of the biphenyl changes appreciably. The steric requirements for such an energy-transfer process are undoubtedly greater than for vertical-energy transfers, and the observed difference in the rates with which biphenyl and the "diffusion-controlled" quenchers quench triplet butyrophenone is some measure of this steric effect. An identical explanation has been advanced by Hammond and his co-workers for the behavior of the stilbenes.<sup>5,13</sup>

It was hoped that the triplet energy of propiophenone was sufficiently large that vertical-energy transfer to biphenyl would be possible. Whatever the reason, energy transfer seems to be not much more efficient than from the lower energy triplet butyrophenone.

The quenching results with benzophenone are the most informative. A quenching rate constant of  $2.5 \times 10^8 M^{-1} \text{sec}^{-1}$  suggests that energy transfer may be slightly endothermic.<sup>14</sup> The first problem, then, in determining the true triplet energy of biphenyl involves ascertaining the true triplet energy of benzophenone. Hammond and co-workers<sup>12</sup> have reported that the 0-0 band in the phosphorescence spectrum of benzophenone in hydrocarbon solvents occurs at 68.5 kcal. Kearns and Case, however, have noted a 2-kcal separation between phosphorescence and absorption 0-0 bands.<sup>19</sup> Consequently, the true triplet excitation energy of benzophenone in benzene probably is approximately 69.5 kcal. As pointed out above, with butyrophenone as donor, the rate constant for energy transfer does not seem to exceed  $2 \times 10^9 M^{-1} \text{sec}^{-1}$ . The further decrease by a factor of 8 upon going to triplet benzophenone donor could be compounded of further steric restrictions plus new energetic requirements. Unfortunately, there is no way of guessing the contribution of steric effects alone in depressing the rate of nonvertical-energy transfer when biphenyl must be twisted all the way to its equilibrium triplet geometry. If the further steric effect were minor, the eightfold total rate decrease would imply that energy transfer was approximately 1 kcal endothermic. If, however, severe steric requirements are the major contributor to the total rate decrease, energy transfer could be thermoneutral or even slightly exothermic. Therefore  $69.5 \pm 1.0 \text{ kcal}$  is perhaps the best estimate that can be made for the true 0-0 energy for the  $T^* \leftrightarrow S_0$  transition of biphenyl. Such a value is in good agreement with the suggested interpretation of the spectroscopic data, being somewhat less than midway between the two divergent 0-0 bands.

Since these experiments provide no knowledge of the lifetime of triplet biphenyl, a discussion of the value of

and Phosphorescence," Interscience Publishers, Inc., New York, 1949, pp 299-303.

A. D. Osborne and G. Porter, *Proc. Roy. Soc. (London)*, **A284**, 195.

Figure 6. Spectroscopic (solid lines) and nonspectroscopic (dashed line)  $T^* \leftrightarrow S$  transitions in biphenyl. Curves represent supposed potentials for the two states as a function of dihedral angle  $\theta$  between the rings.

$k_{-q}/k_d'$  obtained from the slope of Figure 4 would not be profitable. As soon as flash spectroscopic studies allow determination of the value of  $k_d'$ , a comparison of  $k_q$  and  $k_{-q}$  values ought to provide an even better estimate of the triplet energy of biphenyl.

**The Triplet State of Biphenyl.** The spectroscopic data and the quenching results considered together indicate that the geometry of biphenyl in its triplet state must differ considerably from that of its ground state. The most stable conformation of ground-state biphenyl depends strongly on the medium. The dihedral angle between the two rings is  $40\text{--}45^\circ$  in the gas phase,<sup>21</sup>  $20\text{--}25^\circ$  in solution,<sup>22</sup> and  $0^\circ$  in the crystalline state.<sup>23</sup> Consequently, the triplet state in solution must deviate considerably from a  $20\text{--}25^\circ$  twist, and a large body of evidence points to a perfectly planar conformation.

*ortho* substituents are well known to increase the dihedral angle in biphenyls and consequently would be expected to make for better quenching if the triplet state were more twisted than the ground state and worse quenching if the triplet state tended toward planarity. The latter effect is observed. In 1944 Lewis and Kasha reported that *ortho* substituents shift the phosphorescence spectrum of biphenyl to higher energies,<sup>24</sup> presumably because of steric crowding in planar excited states.

Hirota has provided seemingly incontrovertible evidence regarding the geometry of triplet biphenyl. He measured the  $T^* \leftarrow S$  absorption spectra of a few compounds by a modified phosphorescence excitation method, in which crystals of the subject compound were doped with a compound of lower triplet energy to trap the excitation.<sup>25</sup> The  $T^* \leftarrow S$  spectrum of biphenyl so obtained displays a 0-0 band at 65.5 kcal in exact

agreement with the highest energy phosphorescence band. Consequently the 65.5-kcal transition in biphenyl must take place between planar conformations of both ground and triplet states. Such a transition is a true 0-0 transition in the crystal, but not in solution where the most stable conformation of the ground state is twisted.

Figure 6 depicts a schematic energy diagram for the various  $T \leftrightarrow S$  transitions in biphenyl in solution, the curves representing potentials for twisting around the C-C bond connecting the two rings. The two vertical solid arrows represent spectroscopic transitions between states of identical geometry, while the slanted dotted line represents the nonspectroscopic transition which can take place in the relatively slow nonvertical energy-transfer process. The potential for twisting triplet biphenyl is steeper than that for the ground state in accord both with theoretical expectations and with the experimental observation that the 0-0 energy is somewhat less than midway between the highest energy phosphorescence band and the lowest energy absorption band.

The combination of spectroscopic and quenching results indicate that the ground-state conformation which possesses the equilibrium geometry of the triplet state is about 4 kcal excited relative to the favored ground-state conformation. Theoretical estimates predict a very shallow potential for twisting the rings in biphenyl,<sup>26,27</sup> and 5 kcal is the largest estimate<sup>27</sup> yet made for the difference between twisted and planar ground-state biphenyl. Of course the impossibility of resolving optical isomers of 2,2'-disubstituted biphenyls unless the *ortho* substituents are extremely bulky is strong experimental evidence for the low activation energy required to twist the rings of biphenyl.

Choosing the maximum at 3790 Å in the  $T^* \leftarrow S$  absorption spectrum of biphenyl as the "lowest energy spectroscopic transition" instead of some point on the long tail out to 4200 Å may have seemed somewhat arbitrary, and in a sense was. With the shallow potential for twisting the rings, a fairly large percentage of ground-state molecules must exist with twists between  $0$  and  $25^\circ$ , and for that matter greater than  $25^\circ$ . For example, if a planar molecule is excited 4 kcal and one twisted  $10^\circ$  only 2 kcal, simple Boltzmann statistics predict that 0.2 and 4% of the ground state molecules will be planar and twisted  $10^\circ$ , respectively, at room temperature. Figure 6 illustrates that  $T^* \leftarrow S$  absorption by biphenyl molecules twisted less than the favored  $20\text{--}25^\circ$  occurs at longer wavelengths than absorption by the majority of molecules which are in the favored ground-state conformation. The long tail, then, most likely is composed of spectroscopic transitions by small percentages of ground-state molecules in nonequilibrium conformations, and is not particularly unusual except in its 400-Å length. The band at 3790 Å is not, then, the lowest energy  $T^* \leftarrow S$  spectroscopic transition occurring in biphenyl, but it is the lowest energy spectroscopic transition from the lowest vibrational-rotational level of the ground state. It is important to note that the suggested interpretation of combined quenching and phosphorescence data implies that it would be incorrect to call some point near 69.5

in the absorption spectrum the 0-0 transition. Absorption at this energy represents a transition between two states both of which are weakly torsionally relaxed.

Since the triplet state of biphenyl seems to be planar, sensitized racemization of optically active biaryls is expected to occur with ease. Mislow has already reported direct photoracemization of several biaryls.<sup>28</sup> In regard, the effects of substituents on the quenching efficiency of biphenyl promise to be very interesting, and  $k_q$ ,  $k_{-q}$ , and  $k_d'$  all ought to vary considerably, and study of such effects is in progress.

The fact that the triplet energy of biphenyl is higher than that of benzophenone can be estimated from its phosphorescence spectrum helps clarify some photochemistry. Zimmerman reported that biphenyl is only  $1/10$ th as effective as benzophenone at quenching the photorearrangement of an  $\alpha,\beta$ -unsaturated ketone.<sup>29</sup> He measured the triplet energy of the ketone as 71 kcal, but found it difficult to reconcile this value with a 65.5-kcal triplet energy for biphenyl. The matter is of some importance because it involves considerable speculation and controversy regarding the nature of the reacting triplets of enones. The higher value for the triplet energy of biphenyl is more consistent with a ketone triplet of 71-kcal ionization energy.

## Experimental Section

**Reagents.** Reagent grade benzene was washed with sulfuric acid, dried, and distilled from phosphorus pentoxide. Reagent isopropyl alcohol was distilled from sodium.

**Materials.** Propiophenone (Eastman) and butyrophenone (Eastman) were distilled under reduced pressure and then recrystallized several times from pentane. Eastman White Label benzophenone was recrystallized from ligroin. Columbia Organics benzophenone required extensive washings with sulfuric acid before distillation and distillation under reduced pressure. Matheson Coleman and Bell benzhydrol was used without further purification. Benzophenone, biphenyl, fluorene, *trans*-stilbene, 2-fluorobiphenyl (Columbia Organics), and 2-chlorobiphenyl (K & K Laboratories) were all recrystallized once from ethanol. Aldrich triphenylene was recrystallized several times until white. The melting points of the solid quenchers checked with those reported in the literature. Aldrich *cis*-stilbene was distilled under reduced pressure. Biperylene was distilled and analyzed by glpc analysis as *cis*- and *trans*-piperylene and 2% cyclopentene. Aldrich 2,5-dimethyl-2,4-hexadiene was recrystallized from itself.

**Absorption Spectra.** A Cary 14 spectrophotometer was employed and solutions were contained in 5-cm cells. Concentration results are presented in Figure 5.

**Preparation of Samples.** For the propiophenone system, one solution 0.50 *M* in propiophenone was prepared by weighing appropriate amount of ketone in a 25-ml volumetric flask and diluting to volume with isopropyl alcohol. Stock solutions 0.020 *M* naphthalene and 0.029 *M* in biphenyl were prepared similarly.

K. Mislow and A. J. Gordon, *J. Am. Chem. Soc.*, **85**, 3521 (1963).  
H. E. Zimmerman, R. G. Lewis, J. J. McCullough, A. Padwa, J. Maley, and M. Semmelhack, *ibid.*, **88**, 159, 1965 (1966).

A 2-ml portion of the ketone solution was pipetted into each of nine 10-ml volumetric flasks, one of which was immediately filled to volume with solvent. From 1 to 4 ml of each of the quencher solutions was pipetted into each of the other flasks before they were filled to volume. Then 2.6 ml of each solution was placed in separate Exax tubes with a syringe. The tubes were standard 13 × 100 culture tubes which had been washed and dried before being constricted about 1 in. from the top to allow sealing. The tubes with the samples in them were attached to a vacuum line and put through three freeze-pump-thaw cycles before being sealed *in vacuo* at 0.002 mm.

Samples were prepared quite similarly for the benzophenone and butyrophenone systems except that benzene was used as solvent and the ketone stock solutions were 0.250, 0.100, or 0.0250 *M* in benzophenone and 1.00 *M* in benzhydrol in the first case and 1.00 *M* in butyrophenone and 0.02–0.03 *M* in tetradecane in the latter.

**Irradiation of Samples.** In any given run degassed tubes containing four different concentrations of each of several quenchers were irradiated in parallel with two or three samples containing only ketone, all for the same length of time. Irradiations were performed in a "merry-go-round" apparatus,<sup>30</sup> consisting essentially of a rotating turntable with the light source and filters at the center and windows of identical area allowing radiation to enter the various sample compartments. This design ensured that the same intensity radiation impinged upon each sample. Since each sample contained the same concentration of ketone, the amount of irradiation absorbed by each sample was identical; since each tube contained the same volume of liquid, the relative amount of reaction in each tube was directly proportional to the quantum yield. Corning No. 7-83 filter combinations were used to isolate the 3660-Å line of a Hanovia 450-w medium-pressure mercury lamp, and a 1-cm path of 0.002 *M* potassium chromate in 5% aqueous potassium carbonate was used to isolate the 3025–3130-Å lines. The entire apparatus was immersed in a water bath, and the temperature during irradiation was maintained at  $25 \pm 1^\circ$ .

**Analyses of Samples.** The disappearance of propiophenone and benzophenone was measured on a Gilford Model 200 spectrophotometer. Samples with no quencher were carried to approximately 50% conversion. Analyses were made at 3400, 3500, 3600, and 3700 Å for benzophenone and 3400, 3450, and 3500 Å for propiophenone. Measured per cent reactions varied by less than 1% at the various wavelengths. The propiophenone and dilute benzophenone samples were analyzed in 10-mm cells, the 0.050 *M* benzophenone samples in 1-mm cells. The dilute ketones did not absorb all the light incident upon them, and corrections for this were made in calculating relative quantum yields.

The photoelimination of butyrophenone was monitored by measuring the yields of acetophenone formed by glpc analysis. All analyses were performed on an Aerograph Model 600-D Hy-Fi with a 6 ft ×  $1/8$  in. column containing 4% QF-1 and 1% Carbowax 20M on 60–80 mesh Chromosorb P, with a column temperature of 105–110° and a nitrogen flow of 30 ml/min. A Leeds and Northrup Model H recorder fitted with a disk integrator allowed the area ratios of acetophenone to tetradecane to be measured with 1% reproducibility. Area ratios were converted to mole ratios by calibrating the column with known mixtures.

**Acknowledgment.** Grants from the National Science Foundation and the Office of Naval Research are gratefully acknowledged. A grant from Research Corporation allowed preliminary work to be begun and is particularly appreciated. Professor Kearns very generously provided preprints of his work.

# Kinetics of Proton Transfer and Tautomerism in Aqueous Diacetylacetone. A Temperature-Jump Investigation

John Stuehr

Contribution from the Max Planck Institute for Physical Chemistry, Göttingen, West Germany, and the Department of Chemistry, Case Western Reserve University, Cleveland, Ohio<sup>1</sup> 44106.  
Received November 25, 1966

**Abstract:** Diacetylacetone (2,4,6-heptanetrione) is a pseudo-acid with a  $pK$  of 7.43. Kinetic measurements with the temperature-jump relaxation technique have been carried out in the acidic and basic pH regions at 25° and ionic strength 0.1. Two concentration- and pH-dependent relaxation times were observed in the millisecond time region: one in acidic and one in basic solutions. The nmr spectra of the solutions established that the predominant anionic species had the structure  $\text{CH}_3\text{COCH}_2\text{COCH}=\text{CO}-\text{CH}_3$  ( $\text{KHE}^-$ ). The structures of the main protonated forms could not be deduced from the nmr data. On the basis of the nmr results and the concentration dependence of the acidic relaxation time, the latter was attributed to the process  $\text{H}^+ + \text{KHE}^- \rightleftharpoons \text{KHKH}$ , where  $\text{KHKH}$  is the triketone form of the acid. The forward rate constant was found to be  $2.6 \times 10^6 \text{ M}^{-1} \text{ sec}^{-1}$ . The mechanism for hydrolysis was found to be considerably more complicated and involved the hydrolysis of two or more anionic species by means of a cyclic mechanism. Only an effective (over-all) rate constant could be measured for the reaction of the molecules with  $\text{OH}^-$ :  $k_{\text{eff}} = 2.5 \times 10^5 \text{ M}^{-1} \text{ sec}^{-1}$ . On a Brønsted plot of  $\log k$  vs.  $pK_a$ , both rate constants correlated well with data for other ketones.

Eigen and his co-workers have amply demonstrated that the rate of "normal" proton transfer in simple acid-base systems is diffusion controlled; that is, the rate-determining step is the diffusion of the partners to a critical distance.<sup>2,3</sup> For such reactions, the rate constant for the reaction of  $\text{H}^+$  with an anion is on the order of  $10^{10}$ – $10^{11} \text{ M}^{-1} \text{ sec}^{-1}$ ; that for the reaction of  $\text{OH}^-$  with a protonated species is on the order of  $10^{10} \text{ M}^{-1} \text{ sec}^{-1}$ . Exceptions to these generalizations are well understood<sup>4</sup> and occur (a) if steric factors reduce the angle acceptable for successful encounter, (b) in systems which are strongly internally hydrogen bonded (e.g., the reaction of  $\text{OH}^-$  with the enol of acetylacetone), (c) within the class of acids known as "pseudo-acids," in which a proton is removed directly or indirectly from a carbon atom. It is with an example of this class that this paper is concerned.

Proton transfers in pseudo-acids are characterized by reaction rates<sup>2,3</sup> which range from "very slow" (e.g., the neutralization of  $\text{CH}_3\text{NO}_2^-$  with  $\text{H}^+$ , which can be observed with conventional techniques<sup>4</sup>) to virtually diffusion controlled. Within a series of closely related compounds, the rates of protonation and hydrolysis are a direct function of the  $pK$  of the acid.<sup>3,5</sup> An important class of pseudo-acids are ketones which can exist in two or more tautomeric forms. The present paper reports the results of a kinetic study, using the temperature-jump relaxation technique, on the triketone diacetylacetone (2,4,6-heptanetrione). This compound can exist in several tautomeric forms both as the molecule and anion. The possibilities<sup>6</sup> are shown in Table I. The symbols  $\text{KH}$  and  $\text{EH}$  refer to keto and enol portions of the molecule, respectively.<sup>7</sup> To date there

has been no detailed investigation of the relative amounts of the various species present nor a study of the mechanism interrelating them.

## Reaction Mechanisms

**Acidic Region.** Eigen, *et al.*,<sup>8</sup> have shown that protonation and deprotonation equilibria in aqueous solutions of tautomeric substances involve a reaction scheme (a) in which the keto and enol forms of the molecule as well as the anion participate. The conversion I–II

III

$\text{EH}$  = enolic form,  $\text{KH}$  = keto form, and  $\text{E}^-$  = enolate anion

involves the recombination of a proton with the enolate to yield the enolic form of the substance. The conversion I–III involves the same partners, but now yielding the ketone. Reaction II–III describes the anion catalyzed keto–enol conversion in which the proton is directly removed from one tautomer by the enolate ion with the generation of the other tautomeric form. This simple mechanism involving only one anion and one each of the keto and enol forms will be shown to be inadequate to explain fully the results obtained in the present work. Nevertheless, the general features of this mechanism and the concentration dependence of the relaxation time apply.

Mechanism a as a whole is characterized by two relaxation times, which may be separated by several orders of magnitude. The shorter of these ( $\tau_1$ ) is associated exclusively with the fast (diffusion-controlled) conver-

<sup>a</sup> Resonance structures for the anion with the charge localized on carbon not shown.

sion I-II during the restoration of which the slower processes remain virtually unchanged. The longer relaxation time ( $\tau_2$ ) is a function of the kinetic parameters for the two slow steps (I-III, II-III) as well as of the equilibrium parameters of the step I-II. When the two steps are widely separated in time, the two relaxation times are<sup>8</sup>

$$\tau_1^{-1} = k_{12}([H] + [E]) + k_{21} \quad (1)$$

and

$$\tau_2^{-1} = \frac{k_{12}K_{\text{EH}}([H] + \frac{[E]}{1+\alpha})}{K_{\text{EH}} + [H] + \frac{[E]}{1+\alpha}} + k_{21} + \frac{k_{23}[E]}{K_{\text{EH}} + [H] + \frac{[E]}{1+\alpha}} \left( [H] + \frac{[E]}{1+\alpha} \right) + k_{32}[E] \quad (2)$$

where the brackets refer to the equilibrium values of the concentrations<sup>9</sup> and the equilibrium constant  $K_{\text{EH}}$  is defined by

$$K_{\text{EH}} = \frac{[H][E]}{[EH]} \quad (3)$$

The quantity  $\alpha$  is a correction term resulting from coupling the slow relaxation time to a rapid indicator equilibrium (to permit the relaxation to be followed by optical means) and is given by

$$\alpha = \frac{[HIn]}{K_{\text{In}} + [H]} \quad (4)$$

where  $K_{\text{In}}$  is the acid dissociation constant for the indicator.

(9) Charges are omitted for simplicity.

**Basic Region.** The simplest reaction scheme (i.e., hydrolysis of an anion to yield enol and keto forms) may be represented by

III

where the conversion I-II represents the (rapid) protonation of the enolate anion to yield the enol. The two (slower) conversions I-III and II-III involve protonation yielding the keto form and the enolate catalyzed interconversion, respectively. The two relaxation times are

$$\tau_1^{-1} = k_{21}([EH] + [OH]) + k_{12} \quad (5)$$

and

$$\tau_2^{-1} = k_{21} \left( \frac{[KH]}{1+\beta} \frac{[OH]}{K'_{\text{EH}} + [OH] + \frac{[EH]}{1+\beta}} + [OH] \right) + k_{12} \frac{[OH]}{K'_{\text{EH}} + [OH] + \frac{[EH]}{1+\beta}} + k_{23}[E] \frac{K'_{\text{EH}} + [EH]/(1+\beta)}{K'_{\text{EH}} + [OH] + \frac{[EH]}{1+\beta}} + k_{32}[E] \quad (6)$$

where  $K'_{\text{EH}}$  is the hydrolysis equilibrium constant<sup>10</sup> of

(10) Throughout this paper, primed symbols will be used to indicate that the equilibrium constant so designated is a hydrolysis equilibrium constant.

the enol form and  $\beta = [HIn]/(K'_{In} + [OH])$  is again an indicator correction term.

## Experimental Section

**Materials.** The disodium salt of diacetylacetone was prepared<sup>11</sup> by the hydrolysis of 2,6-dimethyl- $\gamma$ -pyrone. A solution of 19 g of 2,6-dimethyl- $\gamma$ -pyrone<sup>11</sup> in 100 ml of absolute ethanol was treated with 19 ml of 16 *N* NaOH and slowly brought to boiling. The resultant yellow precipitate was collected, repeatedly washed in cold alcohol, and dried. The residue was recrystallized twice from 95% ethanol, vacuum dried, and stored at  $-10^\circ$ . The spectrum of the fresh salt was found to compare well with that given by Schwarzenbach, *et al.*<sup>12</sup>

It was found necessary to store the compound in a frozen condition prior to use. A pale yellow aqueous solution at pH 13 turned deep red-brown after 4 days, apparently because of polymerization. Acidic solutions showed no visible evidence of instability over short periods of time. During the course of the experimental work, the compound was prepared freshly for each run.

The solutions were made using sufficient 1 *M* KNO<sub>3</sub> to maintain a constant ionic strength of 0.1. The *pK* of diacetylacetone at 25° and zero ionic strength<sup>11</sup> (7.43) was converted to the concentration equilibrium constant at 0.1 ionic strength by using the relation  $K = K^0/\gamma_{\pm}^2$  where  $K^0$  is the zero ionic strength value and  $\gamma_{\pm}$  is the mean ionic activity coefficient. The value<sup>14</sup>  $\gamma_{\pm} = 0.79$  was used, yielding  $K = 6.1 \times 10^{-8}$ . The indicators used in this investigation and their approximate *pK* values<sup>15</sup> at ionic strength 0.1 were methyl red (4.96), chlorophenol red (6.00), phenol red (8.0), cresol red (8.3), and phenolphthalein (9.7).

**Kinetic Measurements.** All kinetic runs were carried out on a temperature-jump relaxation spectrometer similar to that described by Czerlinski and Eigen.<sup>16</sup> The solution temperature was adjusted such that the final temperature (following the jump) was 25°. In each (acid and base) pH region only a single relaxation time was observed in the time range accessible (1 sec–5  $\mu$ sec). The resultant relaxation curves were photographed with a 35-mm camera system. Their relaxation times were evaluated from enlargements made from the negatives. Blank experiments involving only the indicator system, or diacetylacetone solution without indicator, were also carried out.

## Results.

**Kinetic Measurements. Acidic Region.** The results of experiments between pH 5.0 and 6.5 at 25° are shown in Table II. The over-all anion concentration  $[E]_z$  (calculated from the pH and the equilibrium constant) is given in column 4. This number could consist of several different anionic species (*cf.* Table I).

It is clear that the relaxation time is a function of  $[H] + \{[E]/(1 + \alpha)\}$  and not of  $[E]$  or  $[E]^2/(1 + \alpha)$ . Compare, for example, entries 1 and 5 in Table II, which have different enolate concentrations by a factor of 3 but whose relaxation times are within 10% of each other. The indicator correction term brings the two concentration functions (column 7) to about the same value. The differences in these correction terms lie in the pH differences and the change of the indicator (*i.e.*,  $pK_{In}$  differences; see eq 4). A graph of  $\tau^{-1}$  vs.  $[H] + \{[E]/(1 + \alpha)\}$  yields a straight line, the slope of which is  $k_{11} = 2.6 \times 10^6 M^{-1} \text{sec}^{-1}$ . An estimate may be made of  $K_{BH}$ , the equilibrium constant defined by eq 3, by calcu-

<sup>a</sup>  $[H]$  was calculated from the measured pH by dividing the hydrogen ion activity by  $\gamma_{\pm}$  ( $\cong 0.79$ ). <sup>b</sup> MR = methyl red, CPR = chlorophenol red; indicator concentrations =  $2 \times 10^{-4} M$ .

lating the value which would cause a just detectable deviation of the curve from a straight line. The result is  $K_{BH} \geq 1.5 \times 10^{-8}$ . The third term in eq 2 (and hence the conversion II–III) apparently does not make a measurable contribution to the relaxation time at the concentrations and pH's used.

**Basic Region.** The processes occurring in this region were considerably slower than in the acidic region; the measured relaxation times varied between approximately 1 sec and 70 msec (see Table III). The fourth column in Table III tabulates the total concentration of protonated species  $[HX]_z$  calculated from the over-all concentration and the measured pH. A close examination of eq 6 shows that only the first term fits the results in Table III. The fourth term varies directly as  $[E]$ , the enolate concentration. Since above pH 8.5 virtually all the compound is present in this form, a pH-independent relaxation time would result. The third term can assume several limiting forms depending on which terms are large in the denominator, but in no case can the experimentally observed form be obtained. On the other hand, the first term in eq 6 (corresponding to the conversion I–III) fits the observed concentration and pH dependence exactly. A graph of  $\tau^{-1}$  vs.  $C^0$  (over-all concentration) should yield a straight line at constant pH, the vertical intercept of which should be  $k_{11}[OH]$ . Furthermore, if  $K'_{BH} \gg [EH] + [OH]$ , a series of straight lines with slopes virtually independent of pH (since  $1 + \beta \cong 1$ ) will be observed. Figure 1 shows that the linear relationship anticipated clearly holds for the results at pH 8.87. The ratio of the vertical intercept to the hydroxyl ion concentration is  $2.1 \times 10^6 M^{-1} \text{sec}^{-1}$ . If straight lines are drawn through the points at pH 9.2 and 9.4, the division of the observed intercepts by the hydroxyl ion concentration yields the values 2.8 and  $2.7 \times 10^6 M^{-1} \text{sec}^{-1}$ , respectively. The difference between these numbers is not considered significant; as a result it may be concluded that the value  $k_{11}$  is  $(2.5 \pm 0.4) \times 10^6 M^{-1} \text{sec}^{-1}$ .

<sup>a</sup> [OH] was calculated from the measured pH by dividing the hydroxyl ion activity by 0.79. <sup>b</sup> CR = cresol red, PR = propyl red, P = enolphthalein; indicator concentrations, where not indicated in parentheses, were 2 × 10<sup>-5</sup> M. <sup>c</sup> The symbol [HX]<sub>Z</sub> is used to designate total concentration of protonated forms; see Table I.

It can be easily shown that a *single* set of reaction partners (*i.e.*, a single enolate anion and one ketone and one alcohol, respectively) as represented in mechanisms a and b are not sufficient to explain the kinetics in both the acidic and the basic regions. For example, if we assume the action in basic solutions is the hydrolysis given by mechanism b (where KH and EH now refer to a pair of related protonated forms of the molecule; see Table I), the slow relaxation time is given essentially by the first term in eq 6 with  $K'_{EH} \gg [OH] + \{[EH]/(1 + \beta)\}$ . We conclude therefore that  $K'_{EH} = 1.4 \times 10^{-3}$  or larger.<sup>17</sup> This gives  $K_{EH} (= [H][E]/[EH]) \leq 7.1 \times 10^{-12}$ .

Now if the same partners are to account for the relaxation process observed in the acidic pH range, we have simply mechanism a with  $\tau^{-1}$  given by eq 2, and the terms involving  $k_{12}$  and  $k_{23}$  are negligible. The equilibrium constant  $K_{EH}$  for the rapid step I–II is fixed by the basic solution results, and so  $\tau^{-1}$  reduces to

$$\tau^{-1} = k_{12}K_{12} + k_{21} = k_{21}(1 + K_{12}K_{13}) \cong k_{21} \quad (7)$$

Since  $k_{21} = K_{12}k_{13} = k_{13}(6.8 \times 10^{-8})$ ,  $\tau \cong 2 \times 10^7/k_{13}$ . If  $k_{13}$  is between the (reasonable) values  $10^4$ – $10^7$  M<sup>-1</sup> s<sup>-1</sup> (see Figure 3), then  $\tau$  would lie between 2 and 100 sec and be independent of concentration and pH. Thus, the acidic analog of the basic relaxation time could not yield an observable relaxation in the acidic pH range.

(17) If only part of the protonated form exists as the ketone,  $[KH]/[HX]_Z$  where  $f$  is the fraction of HX in the form KH.

**Nmr Measurements.** The proton resonance spectra of diacetylacetone (determined at room temperature on an A-60 nmr spectrometer) in the basic and acidic

Figure 1. Variation of the relaxation time in basic solutions with the over-all concentration at several pH values.

pH regions are shown in Figure 2. The spectrum of a 1 M solution of acetylacetone at pH 4 was also run for comparison. The latter showed four peaks in the proper ratios to account for 85% ketone and 15% enol in aqueous solution. The resonances for the groups  $\text{CH}_2\text{C}=\text{}$ ,  $\text{CH}_3\text{C}=\text{}$ ,  $-\text{CH}_2-$ , and  $-\text{CH}=\text{}$  occur at 1.95, 2.14, 3.72, and 5.60 ppm, respectively, relative to TMS. The spectrum for the anions of diacetylacetone

Figure 2. Nmr spectra of 0.5 *M* diacetylacetone: upper spectrum, pH 4.0; lower spectrum, pH 10.0 (water resonances are not shown).

indicates also only four peaks, associated with the above-mentioned groups in the ratio 3:3:2:1. The only structure consistent with the latter is the anionic form  $\text{KHE}^-$  (see Table I); *i.e.*, of the three anions possible,  $\text{KHE}^-$  is the only one detectable<sup>18</sup> by nmr. The more complicated acidic spectrum shows once more two different methyl peaks, but in addition there are several other peaks, the integrals of which are in no simple proportions to each other. The only conclusion that can be reached is that the protonated species exists as a mixture of various forms.

## Discussion

While it is clear that one of the two relaxation times observed is associated with the direct protonation of the enolate anion and the other with the hydrolysis of one or more protonated forms, it is desirable to relate the relaxation phenomena to specific species.

The mechanism interrelating all species in Table I is given for the basic pH region by (c) where the slow

steps are represented by arrows and the rapid equi-

(18) Presumably the species  $\text{EHE}_1^-$  and  $\text{EHE}_2^-$  are also present, but at much smaller concentrations.

libria by = signs. The analogous reaction scheme for the acidic region is (d). Although there are eight equilibria shown in these two mechanisms, there can be no more than seven relaxation times for each, since the circular interconnection reduces the number of independent concentration variables by one. There are only two long relaxation times: one is associated with the isolated slow step I–III (and the equilibria preceding it); the other is associated with the “parallel” pathways<sup>19</sup> II–VII and IV–V. The task remains of making an assignment of the observed relaxation times to specific steps. The following observations are relevant.

1. Only two relaxation times were observed, one each in the basic and acidic pH regions. If, for example, the effect in basic solutions corresponds to the processes II–I–III, it is clear by the analysis above (eq 7 and text) why the exact acidic counterpart ( $\text{KHEH}_2 = \text{KHE}^- + \text{H}^+ \rightleftharpoons \text{KHKH}$ ) would not be observed in the acidic solutions. Thus, of the four slow steps in mechanisms c and d, all are needed to account for the two times.

2. The magnitude of the relaxation effect is *ca.* tenfold larger in the acidic region than in the basic region. In both pH regions, the size of the effects decreases as the quantities  $[\text{HX}]_2$  and  $[\text{E}]_2$  decrease relative to  $[\text{OH}]$  and  $[\text{H}]$ , respectively.<sup>20</sup> In the acidic region, the relaxation effect disappears just as  $[\text{E}]_2$  decreases to become virtually identical with  $[\text{H}]$ . The effect in the basic region, however, is much smaller to begin with and disappears well before the sum of the protonated species becomes small compared to  $[\text{OH}]$ .

Both observations are consistent with the assignment of the relaxation effect in acidic solutions to equilibria involving major constituents; in basic solutions, to equilibria involving minor constituents. The best assignment of relaxation times is that shown by the position of  $\tau_a$  (acidic) and  $\tau_b$  (basic) in mechanisms c and d. The final mechanism in the acidic region then becomes

the slow relaxation time ( $\tau_a$ ) of which is given by eq 5, where now

$$\frac{1}{K_{\text{EH}}} = \frac{1}{K_{12}} + \frac{1}{K_{14}} = \frac{[\text{KHEH}_1] + [\text{KHEH}_2]}{[\text{H}][\text{KHE}]}$$

Under the condition  $K_{\text{EH}} \gg [\text{H}] + [\text{KHE}]/(1 + \alpha)$ , this reduces to the experimentally observed form. It is also apparent that since  $\text{KHE}^-$  is the only major anion present (see nmr results), its concentration is virtually equal to the total anion concentration. We conclude therefore that the rate constant  $k_{12}$  has the value  $2.6 \times 10^6 \text{ M}^{-1} \text{ sec}^{-1}$  and  $K_{\text{EH}} \geq 1.5 \times 10^3$  (see acid results).

The interpretation of the relaxation observed in the basic region is somewhat more involved. If one

(19) They are effectively parallel because of the rapid interconversion between states VII and V on the one hand and between II and IV on the other.

(20) The optimum conditions for observing a reaction coupled to a pH indicator are  $[\text{OH}] \ll [\text{HX}]$  in the basic region and  $[\text{H}] \ll [\text{E}]$  in the acidic region, where the symbols  $\text{HX}$  and  $\text{E}^-$  refer to the reactants which yield the relaxation effect.

$$\frac{\bar{k}[\text{OH}]\left[K'_{14}\frac{[\text{KHEH}_1]}{1+\beta}(1+K_{42})(1+K_{57})+K'_{14}K'_{56}+(1+K_{57})K'_{14}\frac{[\text{EHEH}_2]}{1+\beta}+[\text{OH}]\right]}{[\text{OH}]\left\{(1+K_{57})\frac{[\text{KHEH}_1](1+K_{42})+[\text{EHEH}_2]}{1+\beta}+[\text{OH}]+K'_{14}(1+K_{42})+K'_{56}(1+K_{42})\right\}+R} +$$

$$\frac{\bar{k}[\text{OH}]\left[\frac{[\text{KHEH}_1](1+K_{42})+[\text{EHEH}_2]}{1+\beta}+[\text{OH}]+K'_{14}(1+K_{42})\right]}{[\text{OH}]\left\{(1+K_{57})\frac{[\text{KHEH}_1](1+K_{42})+[\text{EHEH}_2]}{1+\beta}+[\text{OH}]+K'_{14}(1+K_{42})+K'_{56}(1+K_{42})\right\}+R} \quad (8)$$

the equilibrium V-Va in mechanism d, the on time  $\tau_b$  becomes<sup>21</sup> as shown in eq 8. The equilibrium constants are defined as

$$K'_{14} = \frac{[\text{KHEH}_1][\text{OH}]}{[\text{KHE}]}, \quad K_{57} = \frac{[\text{EH}_2\text{E}]}{[\text{EH}_1\text{E}]}$$

$$K'_{56} = \frac{[\text{EHEH}_2][\text{OH}]}{[\text{EH}_1\text{E}]}, \quad K_{42} = \frac{[\text{KHEH}_2]}{[\text{KHEH}_1]}$$

Effective rate constants (characterizing the pathways IV-V and II-VII) are given by  $\bar{k} = K_{42}k_{57}$  and  $\bar{k} = k_{54} + K_{57}k_{72}$ . The term  $R$  in the denominator contains all terms not multiplied by

$$+ K_{42}) \times \frac{+ K_{57}[\text{EHEH}_2] + K'_{56}[\text{KHEH}_1] + K'_{14}K'_{56}}{1 + \beta}$$

Eq 8 may reduce to several forms depending on assumptions made concerning the relative values of the terms in the denominator. It is clear that the  $R$  must be large compared to those multiplied by  $\beta$  in order that the experimentally observed form be obtained. In addition, if  $K'_{14}K'_{56}$  is the largest term in the brackets in the expression for  $R$ , there finally

$$\frac{\bar{k}[\text{OH}]}{1 + K_{42}} \times \frac{K'_{57}[\text{EHEH}_2] + [\text{KHEH}_1] + [\text{KHEH}_2]}{K'_{56}(1 + \beta)} + 1 \left] + \frac{1}{K'_{56}} \left[ \frac{[\text{KHEH}_1]}{1 + \beta} + \frac{[\text{EHEH}_2]}{(1 + K_{42})(1 + \beta)} + K'_{14} \right] \quad (9)$$

Equation now has the correct concentration dependence. From Figure 1 the over-all rate constant  $\bar{k}/(1 + K_{42}) = 2.5 \times 10^5 \text{ M}^{-1} \text{ sec}^{-1}$  and  $1 + K_{42} = 7.5 \times 10^3$ . It is not possible to decide unambiguously which of the terms ( $k_{46} + K_{42}k_{57}$ ) in the denominator makes the larger contribution.

It might be asked if the assignment of relaxation times to the acidic and basic regions could just as well be reversed; i.e., is there any ambiguity in the assignment of  $\tau_b$ ? If one were to interchange the two times, the assignment is immediately apparent. The time  $\tau_b$  should indeed be accounted for by step I-III coupled with I-II. The acidic  $\tau$ , however, can easily be shown to be completely inconsistent with the

Figure 3. Brønsted plot for acid and base rate constants in some ketones: solid circles, diacetylacetone; others, (1) barbituric acid, (2) Meldrum's acid, (3) acetylacetone, (4) ethylacetylacetone, (5) diethylmalonic acid, (6) acetone. Upper curve is  $k_a$ , lower is  $k_b$ .

parallel paths V-IV and VII-II. If one again neglects the equilibrium V-Va, an expression for  $\tau_a$  analogous to eq 8 is obtained where now  $\bar{k} = k_{57} + K_{42}k_{57}$ . In order to obtain an equation of the proper form, it is necessary to assume that an "R" term<sup>22</sup> in the denominator is negligible. This requires, among others, that  $K_{56} \ll [\text{H}]$ . On the other hand, it is also required that  $K_{56} \geq 1.5 \times 10^{-3}$  (see acid results), a result which is irreconcilable with the lower limit of  $K_{56}$  necessary in the denominator. Thus we conclude that the assignment of the relaxation times in the acidic and basic regions can be unambiguously made.

It is now well established that a correlation exists between the rate constants for proton transfer in pseudo-acids and the  $pK_a$  of the system (Brønsted relation). Figure 3 shows a Brønsted plot for a series of closely chemically related pseudo-acids.<sup>24</sup> Most of the rate constants have been directly measured;<sup>25</sup> i.e., they are not obtained from the ionization rate and the  $pK_a$ . The acid recombination rate constants all lie on a smooth curve, with the result for diacetylacetone falling precisely where expected. Data are more scanty for the basic reaction ( $\text{HB} + \text{OH}^-$ ); it is clear, however, that the basic rate constant involving diacetylacetone correlates well with a linear extrapolation of the other points. This correlation is remarkable inasmuch as the value measured was an effective or over-all

(23) Containing all terms not multiplied by  $[\text{H}]$ .

(24) If all rate data for acids of varying chemical composition (e.g., trifluoroacetylacetone, nitromethane) were examined, the qualitative correlation would still exist, but several curves would be necessary to adequately represent all the data. For example, the reaction of  $\text{OH}^-$  with  $\text{HCN}$  ( $pK = 9.1$ ) is just 10-fold less than diffusion-controlled: J. Stuehr, *et al.*, *J. Chem. Phys.*, **38**, 587 (1963).

#### Appendix

It requires that  $K'_{56} \gg (1 + K_{57})[\text{EHEH}_2]$  and  $K'_{14} \gg$

rate constant (see eq 8). There are at least three explanations: (1) the correlation is purely fortuitous; (2) the  $pK$  of the molecules involved is also about 7.4; or (3) the basic reaction involves the same molecule or anion<sup>25</sup> as the acidic. The latter is eliminated, however, by the fact that an examination of mechanism c shows that there is no anion or molecule common to two slow processes. For the second possibility, we must have a single step predominating, a condition which is fulfilled either if  $K_{43} \gg 1$  (in which case  $k_{\text{eff}} \cong k_{27}$ ) or  $K_{43} \ll 1$  ( $k_{\text{eff}} \cong k_{45}$ ).

In such a relatively complicated system, it was clearly necessary to have carried out measurements in both pH regions. If measurements had been restricted to acidic solutions, one would have concluded that virtually any two-step mechanism could account for the results.<sup>26</sup> The kinetic parameters for acidic and basic diacetylacetone are summarized in Table IV. Thus, by carry-

**Table IV.** Equilibrium and Rate Constants for Aqueous Diacetylacetone at 25° and 0.1 Ionic Strength

\* Estimated on the basis of diffusion-controlled reactions. <sup>b</sup> Internally hydrogen-bonded molecules hydrolyze with rates ranging from the diffusion-controlled limit to considerably more slowly.  
<sup>c</sup> Over-all rate constant defined by eq 8.

ing out and interpreting measurements in both pH regions, the general features of the protonation-deprotonation mechanism could be established with a high degree of certainty.

(25) But not both; see eq 7 and related text.

(26) For example, a mechanism consisting of one protonated form and two anions ( $E_1^- + H^+ = KH \rightleftharpoons E_3^- + H^+$ ) is easily shown to be compatible with the acid results. The relaxation time for an analogous hydrolysis, however, cannot be fitted to the observed concentration dependence.

## Appendix

**Derivation of Eq 8.** For a small perturbation from equilibrium ( $\delta C_i \ll C_i$ ), the rate of restoration of equilibrium for the parallel paths IV-V and II-VII is given by

$$\frac{d(\delta C_5 + \delta C_6 + \delta C_7)}{dt} = -\frac{d(\delta C_1 + \delta C_4 + \delta C_8)}{dt} = k_{45}(C_4\delta C_{OH} + C_{OH}\delta C_4) + k_{27}(C_2\delta C_{OH} + C_{OH}\delta C_2) - k_{54}\delta C_5 - k_{72}\delta C_7 \quad (\text{A-1})$$

where the symbols  $C_i$  refer to the concentrations of the chemical species indicated in mechanism c. This equation may be put in the form

$$\frac{d\delta C_i}{dt} = -\frac{1}{\tau}\delta C_i \quad (\text{A-2})$$

by using the conservation relationships

$$\sum_{i=1}^6 \delta C_i = 0 \quad (i \neq 3) \quad (\text{mass conservation}) \quad (\text{A-3})$$

$$\delta C_2 + \delta C_4 + \delta C_6 + \delta C_{H_2O} = 0 \quad (\text{proton conservation}) \quad (\text{A-4})$$

$$\delta C_{OH} + \delta C_{H_2O} = 0 \quad (\text{hydroxyl conservation}) \quad (\text{A-5})$$

and the preequilibrium relationships

$$K_{56}\delta C_5 = C_6\delta C_{OH} + C_{OH}\delta C_6 \quad (\text{A-6})$$

$$K_{14}\delta C_1 = C_4\delta C_{OH} + C_{OH}\delta C_4 \quad (\text{A-7})$$

$$\delta C_2 = K_{43}\delta C_4 \quad (\text{A-8})$$

$$\delta C_7 = K_{27}\delta C_5 \quad (\text{A-9})$$

The elimination of all  $\delta C_i$  variables except one from eq A-3-A-9 and substitution into A-1 yields an equation of the form of eq A-2, from which  $\tau^{-1}$  (eq 8) follows directly.

Swift for his part in obtaining and interpreting the nmr spectra.

# Nuclear Magnetic Resonance Spectrum of Oriented (Cyclobutadiene)iron Tricarbonyl<sup>1</sup>

Costantino S. Yannoni, Gerald P. Ceasar, and Benjamin P. Dalley

Contribution from the Department of Chemistry, Columbia University, New York, New York 10027. Received February 18, 1967

**Abstract:** The geometry of the four-proton system in (cyclobutadiene)iron tricarbonyl has been determined from the proton magnetic resonance spectrum in liquid crystal solution. The observed spectrum is characteristic of a geometry with only two independent direct magnetic dipole coupling constants. The observed splittings do not quite fit those expected from a square geometry. The possibility of a rectangular proton configuration was considered. This geometry could be a result either of a stable structure in the isolated molecule or a distortion of a square structure by the nematic solvent. Using a computer simulation program, it was possible to fit the observed spectrum with a rectangle in which the ratio of unequal sides is  $0.9977 \pm 0.0045$ . Assuming reasonable bond lengths and coplanarity of the carbon and hydrogen skeletons, this corresponds to a change of  $0.5^\circ$  in the C-C-H angle. At worst, this is a very small departure from square symmetry and represents a limit on the extent to which the proton geometry can be rectangular and still yield a spectrum consistent with experimental results. The alternative possibility of a proton configuration rotating rapidly in the asymmetric force field of the liquid crystal environment is also considered.

In 1956, Longuet-Higgins and Orgel<sup>2</sup> predicted the stability of complexes of cyclobutadiene with transition metal carbonyls. In 1965, Pettit<sup>3</sup> reported a thesis of the first stable cyclobutadiene complex, (cyclobutadiene)iron tricarbonyl, CIT (see Figure 1). The geometry of the cyclobutadiene system is unknown, but for this reason, it is of interest to study the proton configuration. Analysis of the nmr spectra of molecules dissolved in a nematic liquid crystal solvent can lead to a determination of the anisotropic magnetic dipole coupling constant.<sup>4</sup> Since the anisotropic dipole-dipole interaction is sensitive to interproton distances, it is possible to study the proton geometry by analysis of the nematic pmr spectrum.

## Nematic Four-Spin Spectra

A method for analysis of nmr spectra of molecules in a nematic solution has been developed by Saupe,<sup>4</sup> and the nematic pmr spectrum of CIT was predicted assuming that the protons are in a square and a rectangular configuration. In both structures, the degree of orientation of the molecule (and therefore of the proton system) is given by a single parameter  $S_{33}$ , which is defined as

$$S_{33} = \frac{1}{2} \langle 3 \cos^2 \theta - 1 \rangle$$

where  $\theta$  is the angle between the magnetic field and the molecular symmetry axis (see Figure 1). The brackets signify a time average of the angular function. The diagonal Hamiltonian for the four protons, modified for partial orientation in a liquid crystal matrix, is for a rectangle (in cps)

$$\mathcal{H}^{(1)} = \frac{\gamma^2 \hbar}{4\pi} S_{33} \sum_{i < j}^4 (3I_{zi}I_{zj} - \vec{I}_i \cdot \vec{I}_j) R_{ij}^{-3}$$

where  $\gamma$  is the proton gyromagnetic ratio, and  $R_{ij}$  is the distance between nuclei  $i$  and  $j$ . For a square proton configuration, the Hamiltonian is

$$\mathcal{H}^{(1)} = \frac{\gamma^2 \hbar}{4\pi R^3} S_{33} \sum_{i < j}^4 (3I_{zi}I_{zj} - \vec{I}_i \cdot \vec{I}_j)$$

where  $R$  is the ortho internuclear distance. For both cases, the Zeeman Hamiltonian is

$$\mathcal{H}^{(0)} = -\frac{\gamma H_0}{2\pi} (1 - \sigma - 2S_{33}\Delta\sigma/3) \sum_{i=1}^4 I_{zi}$$

$H_0$  is the magnitude of the external field,  $\sigma$  is the isotropic average of the chemical shift tensor, and  $\Delta\sigma$  is the difference between the chemical shift measured perpendicular and parallel to the four-proton plane. Symmetric eight- and ten-line spectra are predicted for the square and rectangular structures, respectively. The splittings and intensities for both cases are given in Table I. The center of symmetry of both spectra is given by

$$\nu = \frac{\gamma H_0}{2\pi} (1 - \sigma - 2S_{33}\Delta\sigma/3)$$

## 2. Experimental Section

The nematic pmr spectrum of CIT was obtained in a 25 mole % solution of 4,4'-di-*n*-hexyloxyazobenzene at  $76^\circ$  and is shown in Figure 2. It appears to be a symmetric eight-line multiplet. Tetramethylsilane was used as an internal reference. The measured splittings and intensities are given in Table II. Intensities were obtained with a Varian V-3521 integrator.

## 3. The Proton Geometry

**(a) Square Structure.** A visual examination of the spectrum (see Figure 2) would lead to the conclusion that the protons are in a square configuration since there are eight lines. Normalized to the smallest splittings ( $\Delta S_4$  and  $\Delta\nu_4$ ), the four splittings are

Theoretical (Table Ia)	1:2.80944:4.6561:6.65611
Experimental (Table II)	1:2.699 $\pm$ 0.107:4.8 $\pm$ 0.17:6.493 $\pm$ 0.25

It can be seen that, within experimental error, the observed splittings are not quite in the same ratio as the

Figure 2. Nematic proton nmr spectrum of (cyclobutadiene)iron tricarbonyl.

theoretical splittings. The possibility that the spectrum actually consists of ten lines, two pairs of which are unresolved (*i.e.*, that the structure is a rectangle), was then considered. An estimate was made of the extent to which the proton structure could differ from a square (*i.e.*, become rectangular) and still fit the observed spectrum.

(b) Rectangular Structure. A possible continuous transition from square to rectangle may occur as

In this case,  $R_{12}$  becomes less than  $R_{14}$ . Since  $B_{ij} = 3\gamma^2\hbar S_{ij}/4\pi R_{ij}^3$ ,  $B_{12}$  becomes greater than  $B_{14}$ . If the proton chemical shift anisotropy is assumed to be negative,  $S_{33}$  must be positive to explain the relative position of the isotropic and nematic spectra. Then, since  $R_{12} > R_{14} > R_{23}$ ,  $B_{12} < B_{14} < B_{23}$ . Using these inequalities, the transition of the stick-plot spectrum from square to rectangle was made and is shown in Figure 3. The only difference between the two spectra is that the innermost line pair,  $S_4$ , in the "square" spectrum splits into the two "rectangular" line pairs,  $R_4$  and  $R_5$ . The separation between lines in the two pairs (on the same side of the center of symmetry) is given by (see Figure 3 and Table Ib)

$$\frac{1}{\pi}(B_{12} - B_{14}) = \frac{1}{2}(\Delta R_4 - \Delta R_5) \quad (1)$$

Figure 3. Change in nmr spectrum of four protons as structure changes from a square to a rectangle.

Experimentally, only four pairs of lines are obtained, and the half-width at half-height of the innermost pair is 3.0 cps. It was assumed that a line of the inner-

$R_3$	$\Delta R_3 = \frac{1}{3\pi} [(B_{23} + B_{13} + B_{14})^2 + 4(B_{12} - B_{13})^2 + (B_{12} - B_{14})^2 + (B_{13} - B_{14})^2]^{1/2}$	3
$R_4$	$\Delta R_4 = \frac{1}{\pi}(B_{12} + B_{13} - B_{14})$	1
$R_5$	$\Delta R_5 = \frac{1}{\pi}(-B_{12} + B_{13} + B_{14})$	1

<sup>a</sup> See Figure 3.

Table II. Observed Splittings and Intensities in the CIT Proton Nmr Spectrum

Splitting, cps	Intensity
$\Delta\nu_1 = 331.15 \pm 2.25$ (outermost pair)	2
$\Delta\nu_2 = 227.88 \pm 1.66$	1
$\Delta\nu_3 = 137.67 \pm 1.57$	3
$\Delta\nu_4 = 51.00 \pm 1.93$ (innermost pair)	2

most (observed) pair is actually a superposition of two "unresolved" lines. The separation between these two "unresolved" lines is given by eq 1. In order to place

nit on this separation, it is necessary to find the inimum splitting which is possible between two overing lines (i.e.,  $R_4$  and  $R_5$ ) which are not resolved. this purpose, a computer simulation program was l. The lines were given a Lorentzian shape and lf-width at half-height of 3.0 cps. It was found the maximum separation consistent with experit is 1.0 cps. Using (1), the following relation then is

$$\frac{1}{\pi}(B_{12} - B_{14}) \leq 1.0 \text{ cps} \quad (2)$$

n  $B_{12} - B_{14} = 0$ , the proton configuration is a re. Thus, (2) places an upper limit on the distortfrom a square structure. The separation between outer pairs,  $R_1$  and  $R_2$ , is given by (see Table Ib)

$$\Delta R_1 - \Delta R_2 = \frac{2B_{12}}{\pi} \quad (3)$$

splitting between the outermost pair is given by Table Ib)

$$\Delta R_1 = \frac{1}{\pi}(B_{12} + B_{13} + B_{14}) \quad (4)$$

racting (3) from (4), the following is obtained.

$$\frac{1}{\pi}(B_{12} + B_{14}) = \Delta R_1 - \frac{1}{2}(\Delta R_1 - \Delta R_2) \quad (5)$$

ind the maximum departure from the square struc-  
 $\frac{1}{\pi}(B_{12} - B_{14})$  is set equal to the limiting value of 1.0

Using the observed splittings (Table II), eq yield the following dipolar coupling constants (cps): =  $440.64 \pm 4.18$ ,  $B_{12} = 162.23 \pm 4.40$ ,  $B_{14} = 437.50 \pm 18$ . Under the above assumptions, these param- fit the observed splittings.

ratio of the interproton distances,  $R_{12}/R_{14}$ , is a nignful estimate of the distortion of a square struc- since  $R_{12}/R_{14} = 1$  for a square. Since  $B_{ij} = S_{33}/4\pi R_{ij}^3$ , this ratio can be obtained for the imum distortion from a ratio of the above dipolar ling constants.

$$\frac{R_{12}}{R_{14}} = \left(\frac{B_{14}}{B_{12}}\right)^{1/3} = 0.9977 \pm 0.0045$$

vorst, this represents a very small departure from re symmetry and places a limit on the extent to h the structure can depart from square symmetry still fit the observed spectrum.

ther work points to a square structure for the car- skeleton.<sup>5</sup> A square configuration for the protons ld then be reasonable. Assuming that this is the t stable geometry in the isolated molecule, the wing explanation for the distortion is offered: a e is exerted on the C-H bonds as the molecule oles in the nematic solvent, and this squeezes the ons into a rectangular configuration. This ex- ation has been used on the distortion of the C-H ls in the methyl groups of tetramethylsilane in the e solvent.<sup>6</sup> The changes are of the same magni- (~0.5° change in the C-C-H angle). It is im-

Figure 4. Rotation of the distorted cyclobutadiene ring in an asymmetric liquid crystal force field.

portant to note here that if the line widths were smaller, the maximum separation without resolution (eq 2) and the deviation from square structure would be smaller. It is expected that this would be the case with better sample temperature homogeneity.

(c) **Rotationally Averaged Structure.** The alternative possibility that the four-proton system is rotating rapidly in an asymmetric force field due to the liquid crystal environment was then considered. It is assumed that the anisotropy in distortion is such that the four protons are squeezed into a rectangle, the long side of which is parallel to the external field direction. The change in proton geometry as the cyclobutadiene ring rotates about its symmetry axis is shown in Figure 4. The four orientations shown are 90° apart in the angle between the external field direction and a given internuclear vector. It can be seen that the para internuclear distance ( $R_{12}$  and  $R_{34}$ ) remains constant in magnitude during a rotation, while the ortho distance ( $R_{13}$ ,  $R_{23}$ ,  $R_{34}$ , and  $R_{14}$ ) is averaged

$$\langle R_{\text{ortho}} \rangle = \frac{1}{2}(R_{12}^A + R_{12}^B)$$

This leads to a dipolar Hamiltonian modified for this type of distortion and rotational averaging

$$\mathcal{H}^{(1)} = (\gamma^2 \hbar / 4\pi S_{33}) \left[ \langle R_{\text{ortho}}^{-3} \rangle \sum_{i < j} (3I_i I_j - \bar{I}_i \cdot \bar{I}_j) + R_{\text{para}}^{-3} \sum_{k < l} (3I_k I_l - \bar{I}_k \cdot \bar{I}_l) \right]$$

The first term inside the bracket is summed over all ortho nuclear pairs, and the second term over all para nuclear pairs. The spectrum resulting from this Hamiltonian is almost identical with that predicted for a square. The only difference is that the cube of the ratio of the para-to-ortho internuclear distance (derivable from the observed splittings) is not the same as that in a square. For the square, the following relation holds

$$\left(\frac{R_{\text{para}}}{R_{\text{ortho}}}\right)^3 = 2.828$$

From a least-squares analysis of the observed spectrum, the relation between the averaged distances is

$$\left\langle \left(\frac{R_{\text{para}}}{R_{\text{ortho}}}\right)^3 \right\rangle = 2.72 \pm 0.74$$

Without a more detailed knowledge of the force fields which produce the distortion, it is difficult to interpret the above result.

#### 4. Scalar Nuclear Coupling

The scalar nuclear spin-spin coupling has been neglected in the preceding analysis. In a complete analysis, only the most intense line pair ( $S_3$  or  $R_3$ , Table I) is dependent on this parameter. Since the structure is very close to a square, and since the dependence on  $J_i$  of the lines in the pair  $S_3$  is much simpler than in the pair  $R_3$ , only  $S_3$  will be considered. When scalar coupling is included in the spin Hamiltonian the line pair,  $S_3$ , is actually two pairs of lines, the separation between the lines in the two pairs (on the same side of the center of symmetry) being given by

$$\frac{1}{2}(\Delta S_{3a} - \Delta S_{3b}) = 3J_{12} = 3J_{\text{ortho}} \quad (\text{cps})$$

where  $\Delta S_{3a}$  and  $\Delta S_{3b}$  would be the splittings between the two pairs of lines if they could be resolved. Again, since the most intense lines appear to be singlets (see Figure 2), it is only possible to put a limiting value on their separation (without resolution), and hence on  $J_{\text{ortho}}$ . Using computer simulation (see section 3b), this was estimated to be 4.0 cps, so that  $3J_{\text{ortho}} \leq 4.0$  cps and  $J_{\text{ortho}} \leq 1.3$  cps. Because of line-width effects (see preceding section), it is likely that  $J_{\text{ortho}}$  is even

smaller. This result agrees with experimental observations by Pettit<sup>7</sup> in the nmr spectrum of a derivative of CIT, in which  $J_{\text{ortho}} = 0.0$  cps.

#### 5. Proton Chemical Shift Anisotropy

The center of the nematic spectrum is 10.8 cps downfield from the isotropic spectrum. In order to estimate the proton chemical shift anisotropy,  $S_{33}$ , must be known. A value for  $S_{33}$  can be calculated by the following procedure: (1) the observed splittings are matched to the theoretical square (see Table Ia) splittings to yield  $S_{33}/R^3$  (this is reasonable since the observed spectrum is very close to that predicted for a square; see section 3a); (2) using C-C and C-H bond lengths of 1.4 and 1.1 Å, respectively, and assuming coplanarity of the carbon and hydrogen skeletons, the interproton distance,  $R$ , is found to be 2.96 Å.  $S_{33}$  then equals  $\pm 0.02$ . Using this value for  $S_{33}$ , a chemical shift anisotropy of  $\pm 13$  ppm is obtained. This is relatively large, being about the magnitude of shift anisotropies observed for acetylenic protons.<sup>8</sup>

**Acknowledgment.** The authors are grateful to Professor R. Pettit for supplying the cyclobutadiene compound.

## Energetics of the Ionization and Dissociation of $\text{Mn}_2(\text{CO})_{10}$ , $\text{Re}_2(\text{CO})_{10}$ , and $\text{ReMn}(\text{CO})_{10}$ <sup>1</sup>

Harry J. Svec and Gregor A. Junk

*Contribution from the Institute for Atomic Research and Department of Chemistry, Iowa State University, Ames, Iowa. Received November 5, 1966*

**Abstract:** The mass spectra of  $\text{Re}_2(\text{CO})_{10}$ ,  $\text{Mn}_2(\text{CO})_{10}$ , and  $\text{ReMn}(\text{CO})_{10}$  have been established and compared with the mass spectra of the monometal carbonyls. The electron-impact ionization potentials and the appearance potentials of the major fragment ions have been measured. These data are used to calculate specific and average bond dissociation energies for the ions. Metal-CO bond energies for  $\text{Re}_2(\text{CO})_{10}^+$  are shown to be greater than those of  $\text{Mn}_2(\text{CO})_{10}^+$ . Metal-CO bond energies for  $\text{ReMn}(\text{CO})_{10}^+$  are related to those observed for the  $\text{Re}_2$  and  $\text{Mn}_2$  compounds. A similar relative scale is predicted for the metal-CO bond energies of the neutral molecules. The calculated metal-metal dissociation energies (ev) of the neutral decacarbonyls and their ions to produce  $\cdot\text{M}(\text{CO})_5$  and  $\text{M}(\text{CO})_5^+$  are: Mn-Mn, 0.96, and  $[\text{Mn-Mn}]^+$ , 0.82; Re-Re, 2.22, and  $[\text{Re-Re}]^+$ , 2.08; Re-Mn, 2.67, and  $[\text{Re-Mn}]^+$ , 2.65. The ionization and dissociation mechanisms are discussed in terms of "isolated ionization" at one of the metal atoms in a dimetal carbonyl, and this model is tested by experimental observations.

Mass spectrometric studies of polynuclear carbonyls<sup>2,3</sup> and derivatives<sup>4a</sup> have been published recently. King<sup>2</sup> has worked primarily with the tri- and tetrametal carbonyls, while Preston and Reed<sup>4a</sup> and Lewis *et al.*,<sup>4b</sup> have concentrated their activities on the derivatives of dimetal carbonyls. No ionization

and appearance potential measurements are reported by these authors. Winter and Kiser<sup>3</sup> report the ionization potentials of  $\text{Mn}_2(\text{CO})_{10}$  and  $\text{Co}_2(\text{CO})_8$ , and the appearance potentials of some fragment ions from these materials are used to calculate  $\Delta H_f(\text{ion})$  values. Fragmentation patterns are also reported. These mass spectral patterns are important for the relationships to the quasi-equilibrium theory<sup>5</sup> and for structural information.<sup>3</sup> However, the energetics of the various fragmentations are also of fundamental importance.

non-impact studies may be used to gain an insight the validity of the proposed bonding in the metal onyls. In addition, conclusions about structure, l on fragmentation pattern correlations, may times be verified by appearance-potential meas- ents. Finally, bond dissociation energies which f thermochemical interest are obtained from elec- impact data.

have measured the energy required to produce ent ions from the decacarbonyls of  $\text{Re}_2$ ,  $\text{Mn}_2$ ,  $\text{ReMn}$  primarily to obtain bond dissociation ener- and to study the mechanisms of ionization and iation. The strength of the metal-CO bonds and metal-metal bonds reported here may not be ably accurate because of unknown kinetic and tion energies. The possible errors due to these s should be about equal for the series,  $\text{Mn}_2(\text{CO})_{10}$ ,  $\text{Re}_2(\text{CO})_{10}$ , and  $\text{ReMn}(\text{CO})_{10}$ . Thus, at least a good ve scale of bond energies is expected.

### Experimental Section

**Instrumentation.** A General Electric mass spectrometer with cations<sup>4</sup> previously described was used to obtain the data d here. No additional modifications were required for this

**Apparent-Potential Measurements.** The vanishing current<sup>7</sup> pro- was used to measure the onset potentials. Simultaneous ng of the dimetal compounds and the xenon voltage cali- gas was used.

**Materials.** The  $\text{Re}_2(\text{CO})_{10}$  and  $\text{Mn}_2(\text{CO})_{10}$  were purchased from rorganics, Inc., and used without further purification. The mple of  $\text{ReMn}(\text{CO})_{10}$  was kindly furnished by Dr. H. D. University of California, Los Angeles, Calif.

### Results and Discussion

**Mass Spectra.** Line diagrams of the 55-ev mass a are shown in Figure 1. Only the dimetal ent ions are shown since these fragments cause of the total ion current. The total intensity of the metal ions is less than 20% of the total dimetal ntensity for each sample. The ratios of these ities are:  $\Sigma \text{Mn}(\text{CO})_x^+ / \Sigma \text{Mn}_2(\text{CO})_x^+ = 0.20$ ;  $\text{CO})_x^+ / \Sigma \text{Re}_2(\text{CO})_x^+ = 0.05$ ; and  $[\Sigma \text{Mn}(\text{CO})_x^+ \text{Re}(\text{CO})_x^+] / \text{ReMn}(\text{CO})_x^+ = 0.12$ . The apparent ence for ruptures of the metal-CO bonds is a ion of the lower strength of these bonds compared he metal-metal bonds. The greater intensity of onometal fragments for the manganese compound its that the metal-metal bond is weaker than the e bond. This conclusion based on the 55-ev spectra is supported by appearance-potential rements discussed in the sections on dissociation es. The enhanced tendency to form the higher ragment from  $\text{Re}_2(\text{CO})_{10}$  compared to  $\text{Mn}_2(\text{CO})_{10}$  s the expected periodic trend in the metal-CO nergies as the molecular weight increases within sition metal group.

numerical tabulation of Winters and Kiser<sup>8</sup>  $\text{Mn}_2(\text{CO})_{10}$  has been converted to the per cent total ion and is included as the broken bar graph in e 1. Their spectrum contains more of the lighter ragment, and this is probably due to a combina- f sampling and instrumental factors.

$\text{Mn}(\text{CO})_5^+$		
$\text{Mn}_2(\text{CO})_8^+ \rightarrow \text{Mn}_2(\text{CO})_7^+ + \text{CO}$	169.5	169.3
$\text{Mn}_2(\text{CO})_8^+ \rightarrow \text{Mn}_2(\text{CO})_6^+ + \text{CO}$	197.1	197.0

currents by varying instrumental parameters such as sensitivity and repeller potential. Others undoubtedly exist, and the observation of these are important because they support the decomposition proposals<sup>3,4b,5,8,9</sup> of successive loss of CO groups in the unimolecular dissociation of metal carbonyls.

A possible rearrangement ion current was observed in the fragmentation of  $\text{ReMn}(\text{CO})_{10}$ . Seven per cent of the total is due to a  $[\text{Re}(\text{CO})_5]^+$  ion current. Rearrangements involving migrations other than hydrogen are rare. Only one other such rearrangement, the OH group migration to form the *m/e* 46 ion current from amino acids,<sup>10</sup> has been positively confirmed at our laboratory. However, recent research reports from

<sup>a</sup> Reproducibility of all AP values reported here are from  $\pm 0.05$  to 0.2 ev. <sup>b</sup>  $\Delta H_f^\circ$  of  $Mn_x(CO)_{10} = -385.9$  kcal/mole from calorimetric measurements: F. A. Cotton and K. R. Mouchamp, *J. Chem. Soc.*, 533 (1960). <sup>c</sup> Values calculated from Winters and Kiser data. <sup>d</sup>  $\Delta H_f^\circ$  of  $Re_x(CO)_{10} \approx -611$  kcal/mole from AP data. No calorimetric value available. <sup>e</sup>  $\Delta H_f^\circ$  of  $ReMn(CO)_{10} \approx -548$  kcal/mole from AP data. No calorimetric value available.

Stanford<sup>11</sup> suggest that migration of bulky groups may occur more frequently than previously suspected. The absence of a comparable rearrangement ion current (if indeed the observed ion current is the result of a rearrangement process) due to a  $M(CO)_6^+$  fragment in the mass spectrum of either  $Mn_x(CO)_{10}$  or  $Re_x(CO)_{10}$  suggests that the structure of  $ReMn(CO)_{10}$  may be considerably different in the spatial configuration of the CO groups.

**Ionization Potentials.** The ionization potentials are recorded in Table II. Our value for  $Mn_x(CO)_{10}$  is in excellent agreement with the value reported by Winters and Kiser.<sup>3</sup> The ionization potentials of the metal atoms are listed in column 4 for comparison. Since the CO ionization potential is about 14.0 ev, it appears as if ionization of these metal carbonyls involves removal of one of the valence electrons from the metal atom.

**Appearance Potentials.** The appearance potentials for the major fragment ions are listed in column 2 of Table III. Values of  $\Delta H_f(\text{ion})$  are tabulated in column 4. For comparison, values calculated from the appearance-potential data of Winters and Kiser<sup>3</sup> are given in parentheses. The decomposition reactions for forming the various dimetal ions are uncomplicated, and the processes listed in column 3 are undoubtedly

correct. However, the reactions for forming the mono-metal fragments are questionable due to at least two possible reaction paths. Hence, no  $\Delta H_f(\text{ion})$  values are recorded for these fragment ions. Calorimetric measurements on  $Re_x(CO)_{10}$  and  $ReMn(CO)_{10}$  have not yet been reported so  $\Delta H_f^\circ$  values for these materials are not available. We have estimated some values (see Standard Heat of Formation section) and these are used in the calculation of the  $\Delta H_f(\text{ion})$  values given for the  $Re_x(CO)_x^+$  and  $ReMn(CO)_x^+$  fragment ions. The appearance potentials for the  $M_x(CO)_x^+$  fragment ions listed in Table III are plotted on the energy diagrams shown in Figure 2. The higher energy required to form each successively lighter fragment ion is experimental confirmation for the proposed stepwise decomposition mechanism.

**Standard Heat of Formation Calculations.** The  $\Delta H_f(Mn_2^+)_g$  listed in Table III is 309 kcal/mole or 13.43 ev. This value can be used to approximate values for  $\Delta H_f(Re_2^+)_g$  and  $\Delta H_f(ReMn^+)_g$  from the fragmentation of their respective decacarbonyls. The approximation is based on the 6.00-ev difference between the  $\Delta H_f(Mn_2^+)_g = 13.43$  ev and the ionization potential of  $Mn(g) = 7.43$  ev. The difference between the ionization potential of  $Re(g)$  and the  $\Delta H_f(Re_2^+)_g$  is also assumed to be 6.00 ev. Since the ionization potential of  $Re(g)$  is 7.87 ev, the value of  $\Delta H_f(Re_2^+)_g$  is estimated to be 13.87 ev. The  $\Delta H_f(ReMn^+)_g$  value is then in-

(11) P. Brown and C. Djerassi, *J. Am. Chem. Soc.*, **88**, 2469 (1966), and references cited therein.

interpolated to be intermediate between the values of  $\text{Re}_2^+$  and  $\text{Mn}_2^+$  or 13.66 eV. These  $\Delta H_f^\circ(\text{ion})$  values and the appearance potentials of  $\text{Re}_2^+$  and  $\text{ReMn}^+$  are used in the equation

$$\Delta H_f^\circ(\text{M}_2^+) = \text{AP}(\text{M}_2^+) - 10[\Delta H_f^\circ(\text{CO})] + \Delta H_f^\circ[\text{M}_2(\text{CO})_{10}]_g \quad (1)$$

to calculate the standard heats of formation. The calculated values are -611 kcal/mole for  $\text{Re}_2(\text{CO})_{10}$  and -548 kcal/mole for  $\text{ReMn}(\text{CO})_{10}$ . It is difficult to estimate the probable error in these values. In the interpolation to obtain the value for  $\Delta H_f^\circ(\text{Re}_2^+)$ , the heat of sublimation of Re and Mn are assumed to be equal. It is also assumed that the metal-metal bond strengths are equal. Both assumptions are erroneous since the  $\Delta H_{\text{sub}}$  for Re and the bond energy of Re-Re are both greater than the corresponding values for Mn. However, in the process

errors due to the assumptions tend to cancel one another. Since the bond-energy error is probably greatest, we consider these heat of formation values for  $\text{Re}_2(\text{CO})_{10}$  and  $\text{ReMn}(\text{CO})_{10}$  to be maximum (negative) values.

**Metal-CO Dissociation Energies.** The specific bond dissociation energies for the various ions have been calculated for the AP data and are listed in Table IV.

Table IV. Specific Bond Dissociation Energies of Ions

Dissociation process	Dissociation energy, eV		
	$\text{Mn}_2$	$\text{Re}_2$	$\text{ReMn}$
$\text{M}_2(\text{CO})_{10}^+ \rightarrow \text{M}_2(\text{CO})_9^+$	0.7 <sup>a</sup>	1.3	0.8 <sup>a</sup>
$\text{M}_2(\text{CO})_9^+ \rightarrow \text{M}_2(\text{CO})_8^+$	0.7 <sup>a</sup>	1.3	0.8 <sup>a</sup>
$\text{M}_2(\text{CO})_8^+ \rightarrow \text{M}_2(\text{CO})_7^+$	0.7 <sup>a</sup>	2.7	0.8 <sup>a</sup>
$\text{M}_2(\text{CO})_7^+ \rightarrow \text{M}_2(\text{CO})_6^+$	0.7 <sup>a</sup>	1.5	0.8 <sup>a</sup>
$\text{M}_2(\text{CO})_6^+ \rightarrow \text{M}_2(\text{CO})_5^+$	0.7 <sup>a</sup>	1.7	0.8 <sup>a</sup>
$\text{M}_2(\text{CO})_5^+ \rightarrow \text{M}_2(\text{CO})_4^+$	2.1	2.6	2.5
$\text{M}_2(\text{CO})_4^+ \rightarrow \text{M}_2(\text{CO})_3^+$	1.4	2.2	2.3
$\text{M}_2(\text{CO})_3^+ \rightarrow \text{M}_2(\text{CO})_2^+$	1.0	2.1	2.8
$\text{M}_2(\text{CO})_2^+ \rightarrow \text{M}_2(\text{CO})^+$	1.2	2.7 <sup>b</sup>	3.2
$\text{M}_2(\text{CO})^+ \rightarrow \text{M}_2^+$	1.2	2.7 <sup>b</sup>	3.0

<sup>a</sup> These are average values calculated from the dissociation of the first five CO groups. <sup>b</sup> These are average values calculated from the dissociation of the last two CO groups.

The almost equal energy required to dissociate the first five metal-CO bonds from  $\text{ReMn}(\text{CO})_{10}^+$  and  $\text{Mn}_2(\text{CO})_{10}^+$  suggests that these dissociations in  $\text{ReMn}(\text{CO})_{10}^+$  are due to Mn-CO bond ruptures. The near-equal energy required to dissociate the last five CO groups from  $\text{ReMn}(\text{CO})_{10}^+$  and  $\text{Re}_2(\text{CO})_{10}^+$  agrees with this suggested process. The negligible intensities of fragment ions between  $\text{M}_2(\text{CO})_{10}^+$  and  $\text{M}_2(\text{CO})_6^+$  (see Figure 1) for both the  $\text{Mn}_2$  and  $\text{ReMn}$  decacarbonyls also support this proposal.

The average metal-CO bond dissociation energies from Table IV are

It is not possible to calculate the dissociation energies of the neutral molecules because of unknown ionization potentials and valence-state excitation energies for

Figure 2. Appearance potentials of  $\text{M}_2(\text{CO})_{10}^+$  ions from  $\text{Mn}_2(\text{CO})_{10}$ ,  $\text{Re}_2(\text{CO})_{10}$ , and  $\text{ReMn}(\text{CO})_{10}$ : solid bar, this report; broken bar, Winters and Kiser.<sup>9</sup>

$\text{Re}_2$ ,  $\text{Mn}_2$ , and  $\text{ReMn}$ . However, it was shown for all the monometal carbonyls<sup>12</sup> that the bond dissociation energies of the ions are 0.3 to 0.5 eV per bond higher than the neutral dissociation energies. If this difference is true for the dimetal carbonyls, the neutral dissociation energies are 0.6, 1.7, and 1.4 eV per metal-CO bond in  $\text{Mn}_2(\text{CO})_{10}$ ,  $\text{Re}_2(\text{CO})_{10}$ , and  $\text{ReMn}(\text{CO})_{10}$ .

**Metal-Metal Dissociation Energies.** The ionization potential of the  $\cdot\text{M}(\text{CO})_5$  radical and the appearance potential of  $\text{M}(\text{CO})_6^+$  from  $\text{M}_2(\text{CO})_{10}$  are required to calculate the metal-metal dissociation energy of the decacarbonyls according to the equation

$$D[(\text{CO})_5\text{M}-\text{M}(\text{CO})_5] = \text{AP}[\text{M}(\text{CO})_6^+] - \text{IP}[\text{M}(\text{CO})_5] \quad (6)$$

Bidinosti and McIntyre<sup>13</sup> have recently measured the ionization potential of the  $\cdot\text{Mn}(\text{CO})_5$  radical and report a value of 8.44 eV, but no measurement of the ionization potential of the  $\cdot\text{Re}(\text{CO})_5$  radical is currently available. However, the difference in the ionization potentials of  $\cdot\text{Mn}(\text{CO})_5 = 8.44$  eV and  $\text{Mn}_2(\text{CO})_{10} = 8.58$  eV is only 0.14 eV. We have assumed that this relationship is valid for  $\cdot\text{Re}(\text{CO})_5$  and  $\text{Re}_2(\text{CO})_{10}$ , and the ionization potential of  $\cdot\text{Re}(\text{CO})_5$  is estimated to be 0.14 eV below the ionization potential of  $\text{Re}_2(\text{CO})_{10}$  (see Table II) or 8.13 eV. These values for the ionization potentials of  $\cdot\text{Mn}(\text{CO})_5$  and  $\cdot\text{Re}(\text{CO})_5$  radicals and the appearance potentials for  $\text{Re}(\text{CO})_6^+$  and  $\text{Mn}(\text{CO})_6^+$  (from Table I) were used in eq 6 to calculate the metal-metal dissociation energies listed in Table V. As expected, the Re-Re

**Table V.** Metal-Metal Bond Dissociation Energies for  $M_2(CO)_{10}$  (Ions and Neutral Molecules)

Process	$\Delta H$ , ev
$(CO)_5Mn-Mn(CO)_5 \rightarrow Mn(CO)_5 + Mn(CO)_5$	0.96 <sup>a</sup>
$[(CO)_5Mn-Mn(CO)_5]^+ \rightarrow Mn(CO)_5 + Mn(CO)_5^+$	0.82
$(CO)_5Re-Re(CO)_5 \rightarrow Re(CO)_5 + Re(CO)_5$	2.22
$[(CO)_5Re-Re(CO)_5]^+ \rightarrow Re(CO)_5 + Re(CO)_5^+$	2.08
$(CO)_5Re-Mn(CO)_5 \rightarrow Re(CO)_5 + Mn(CO)_5$	2.67
$[(CO)_5Re-Mn(CO)_5]^+ \rightarrow Re(CO)_5 + Mn(CO)_5$	2.65
$[(CO)_5Re-Mn(CO)_5]^+ \rightarrow Re(CO)_5 + Mn(CO)_5^+$	... <sup>b</sup>

<sup>a</sup> This value compares favorably with the 0.82-ev value reported by Bidinosti and McIntyre<sup>13</sup> and is considerably lower than the 1.48-ev value calculated by Cotton and Mouchamp (see footnote *b* Table III) from calorimetric measurements. While the explanation for this discrepancy is not yet resolved, the relative scale of bond energies reported here should be reasonably accurate. <sup>b</sup> The low intensity of  $Mn(CO)_5^+$  ion current made appearance-potential measurement unfeasible. For this reason no internal check on the  $ReMn$  dissociation energy calculated from this process was possible.

bond dissociation energy turns out to be greater than the  $Mn-Mn$  bond dissociation energy. The explanation for the even higher value for the bond energy of  $Re-Mn$  may be related to what was observed by Saalfeld and Svec<sup>14</sup> with the dihydride,  $H_2Si-GeH_3$ , in which overlap of vacant d orbitals in the mixed metal compounds tend to stabilize the metal-metal bond.<sup>15</sup> The difference in the electronegativities of  $Mn$  and  $Re$  may also contribute to the strength of the metal-metal bond in the mixed metal compound.

The metal-metal bond energy values of the ions follow the same trend as the neutral molecules, with the mixed compound having the highest value. Although the ions have less bond energy in each case, the difference is rather small indicating that charge has relatively little effect on the metal-metal bond.

**Ionization and Dissociation Mechanism.** It has been suggested that ionization of metal carbonyls<sup>16</sup> involves removal of one of the valence electrons from the metal atom. The highest probability for localization of the resultant positive charge from an "isolated ionization concept"<sup>17</sup> is therefore on the metal atom from which the electron is removed. To test this suggestion, the average dissociation energies of the metal-CO bonds from  $M(CO)_6$ ,  $M(CO)_6^+$ , and  $M_2(CO)_{10}^+$  have been investigated. These dissociation energies, calculated from the appearance-potential data in Tables III and IV and our studies of monometal carbonyls,<sup>13</sup> are listed in column 2 of Table VI. The estimated average dissociation energies are taken from chromium and tungsten hexacarbonyl data.<sup>12</sup> The average metal-CO bond dissociation energy for  $Cr-CO$  and  $Cr-CO^+$  are taken to be roughly equal to that expected for

**Table VI.** Observed and Estimated Dissociation Energies of  $M-CO$  Bonds in Dimetal Decacarbonyls

Proposed process	Dissociation energy, ev	
	Obsd av	Estd av <sup>a</sup>

$Mn-Re^+(CO)_5 \rightarrow Mn-Re^+ + 5(CO)$	2.7	2.3 <sup>e</sup>

<sup>a</sup> Taken from unpublished data from this laboratory. <sup>b</sup> The  $\Delta H$  for the process:  $1/6Cr(CO)_6 \rightarrow 1/6Cr + CO$ . <sup>c</sup> The  $\Delta H$  for the process:  $1/6Cr^+(CO)_6 \rightarrow 1/6Cr^+ + CO$ . <sup>d</sup> The  $\Delta H$  for the process:  $1/6W(CO)_6 \rightarrow 1/6W + CO$ . <sup>e</sup> The  $\Delta H$  for the process:  $1/6W^+(CO)_6 \rightarrow 1/6W^+ + CO$ .

$Mn-CO$  and  $Mn-CO^+$ . The same approximation is made in the case of  $W$  and  $Re$ . The proposed bond ruptures are listed in column 1 of Table VI. No preferred charge localization exists between the metal atoms of the symmetrical carbonyls, and the choice listed is arbitrary. However, the charge is shown on the  $Re$  atom in the case of  $ReMn(CO)_{10}$ . The reason for this choice is the lower ionization potential observed for  $Re_2(CO)_{10}$  compared with  $Mn_2(CO)_{10}$  and the expectation that the lower energy process should occur preferentially. The agreement of the observed dissociation energies and the crudely estimated values suggests that the model proposed for ionization and dissociation is correct.

The almost equal average bond dissociation energy for the loss of the first five CO groups from  $Mn_2(CO)_{10}$  (0.7 ev per bond) and  $ReMn(CO)_{10}$  (0.8 ev per bond) supports this proposal, as does the close agreement of the dissociation of the last five CO groups from  $Re_2(CO)_{10}$  (2.5 ev per bond) and  $ReMn(CO)_{10}$  (2.7 ev per bond). Other observations which support this localized charge proposal are: the similarity of the mass spectra of  $ReMn(CO)_{10}$  to  $Mn_2(CO)_{10}$  from the parent ion to the  $M_2(CO)_5^+$  ion; the similarity of the remainder of the spectrum of  $ReMn(CO)_{10}$  to that observed for the  $Re_2(CO)_5^+$  to  $Re_2^+$  fragment ions from  $Re_2(CO)_{10}$ ; and the high intensity of the  $Re(CO)_5^+$  (100 units) relative to the  $Mn(CO)_5^+$  (<1 unit). Thus, we conclude that the site of ionization of these complex molecules can be considered to be "isolated" and that low-energy processes are favored in the fragmentation; i.e., the metal-CO bonds of the uncharged metal atom are the first to be ruptured. This observation is of fundamental mechanistic importance and should prove useful in future interpretations of the mass spectra of polymetal carbonyls and ligand-substituted metal carbonyls.

**Acknowledgments.** The authors are indebted to Dr. H. D. Kaesz of the University of California, Los Angeles, Calif., for furnishing the pure sample of  $ReMn(CO)_{10}$  and to Mr. William Stebbings for assisting in the data accumulation.

# The Catalytic Addition of Fluorine to a Carbonyl Group. Preparation of Fluoroxy Compounds<sup>1</sup>

Max Lustig, A. R. Pitochelli, and John K. Ruff

Contribution from Rohm and Haas Company, Redstone Research Laboratories, Huntsville, Alabama 35807. Received November 21, 1966

**Abstract:** The low-temperature metal fluoride catalytic fluorination of carbonyl halides and fluoroalkyl acid fluorides provides a simple method for the preparation of fluoroxyfluoroalkanes in high yields. In addition to some known fluoroxy derivatives the new compounds, 1-fluoroxy-1,1,2,2-tetrafluoroethane,  $\text{FOCF}_2\text{CF}_2\text{H}$ , octafluoro-1,4-bis(fluoroxy)butane,  $\text{FO}(\text{CF}_2)_4\text{OF}$ , decafluoro-1,5-bis(fluoroxy)pentane,  $\text{FO}(\text{CF}_2)_5\text{OF}$ , 1-fluoroxy-2-difluoroaminotetrafluoroethane,  $\text{CF}_2(\text{NF}_2)\text{CF}_2\text{OF}$ , and 1-fluoroxy-2-difluoroaminohexafluoropropane,  $\text{CF}_2\text{CF}(\text{NF}_2)\text{CF}_2\text{OF}$ , are also prepared by this method. Some chemical and physical properties of the new compounds are given.

ough the first example of a fluoroxyalkane has been known for 19 years,<sup>2</sup> it was not until recently other members of this class of compounds have prepared.<sup>3,4</sup> The techniques of fluorination employed in these preparations have varied from the high-temperature, catalyzed, flow fluorination of  $\text{CH}_3\text{OH}$ , or  $\text{COF}_2$ , to produce  $\text{CF}_3\text{OF}$  to the lower temperature fluorination of alcohols.<sup>3,4</sup> A new low-temperature fluorination procedure has been developed which, in the presence of a suitable catalyst, permits the condensation of fluorine across a carbon-oxygen double bond. Fluoroxyfluoroalkanes can be prepared in high yields.

## Experimental Section

**Materials.** The perfluoroalkyl acid fluorides were prepared from the corresponding chlorides by reaction with KF in 3-methylphenyl hexafluoroacetone was obtained from General Chemical Co., Allied Chemical Corp., and used without further purification. The difluoroamino acid fluoride derivatives were available from other study.<sup>5</sup>

**Fluorination.** Explosions have been encountered on occasion upon the use of the new bis- and  $\alpha$ -difluoroaminohypofluorites. Workers should be properly shielded.

**General Preparative Procedure.** A 10-g sample of cesium fluoride, which had been dried overnight at 175–200° under vacuum and ground in a nitrogen-filled drybox, was loaded into a 150-ml Hoke cylinder containing approximately 30 3/8-in. diameter stainless steel balls. The cylinder was then shaken for several hours until fine grinding of the cesium fluoride. A 1.72-mmol of  $\text{COF}_2$  was condensed into the reactor at –196°, and fluorine (1.73 mmoles) was allowed to expand into the reactor at room temperature. The reactor was then placed in a –78° dry ice and allowed to stand for 4 hr. After cooling the reactor to –78°, any unreacted fluorine was pumped out through a trap containing KOH. The condensable product was then removed and purified. This procedure was employed for all the compounds at the same temperature and for the same time interval above except for  $\text{HCF}_2\text{C}(\text{O})\text{F}$  (cf. Discussion), which was allowed to react with fluorine at 0°. A summary of the experimental data is given in Table I.

**General Purification Procedure.** Reaction mixtures containing known compounds  $\text{CF}_3\text{OF}$ ,  $\text{C}_2\text{F}_5\text{OF}$ ,  $\text{C}_3\text{F}_7\text{OF}$ , and  $(\text{CF}_3)_2\text{CHO}$  were prepared for analysis first by subjecting them to vapor chromatography using the column recommended in the literature. The <sup>19</sup>F nmr and infrared spectra of the pure components were then compared with those published.<sup>2</sup> Purification of the fluoroxyfluoroalkyl compounds was performed by vacuum-

line fractionation. The butane derivative was retained in a trap set at –126° while the pentane was held in a –95° trap. Any unreacted acyl fluoride was removed by allowing the mixture to stand over water at room temperature for no longer than 0.5 hr. The purification of  $\text{CF}_2\text{CF}(\text{NF}_2)\text{CF}_2\text{OF}$  was accomplished by vacuum-line fractionation through a trap set at –126° in which it was retained. No purification of  $\text{NF}_2\text{CF}_2\text{CF}_2\text{OF}$  was necessary since it was obtained in quantitative yield.

**Analyses.** Although some analyses are given, they were generally difficult to obtain because several of the samples exploded during handling. For the fluorine analysis, samples were reduced with lithium in *n*-propylamine within high-pressure Pyrex tubes containing Fischer-Porter Teflon valves. Conventional techniques were then employed. The Dumas method was used to determine nitrogen in gaseous samples; carbon was determined by the conventional Pregl combustion method using fresh MgO mixed with the catalyst in the combustion tube (see Table I for some results).

**Molecular Weights.** Molecular weights were obtained by vapor density measurements (refer to Table I).

**Melting Points.** The melting points of  $\text{FO}(\text{CF}_2)_4\text{OF}$  and  $\text{FO}(\text{CF}_2)_5\text{OF}$  were measured by immersing samples contained in 5-mm o.d. Pyrex tubes into a 1:1 v/v pentane-isopentane cold bath which was warmed at a rate of ca. 0.5°/min (see Table I).

**Infrared Spectra.** The infrared spectra of the new materials were obtained using gaseous samples in cells having a 10-cm path length employing a Perkin-Elmer Model 21 spectrometer. The following are the frequencies in  $\text{cm}^{-1}$  (relative intensities) for  $\text{FO}(\text{CF}_2)_4\text{OF}$ : 1333 (m), 1284 (s), 1250 (sh), 1227 (vs), 1203 (sh), 1176 (m), 1136 (s), 1096 (w), 1061 (w), 962 (m), 917 (m), 886 (s), 862 (m), 821 (w), 803 (m), 782 (s), 763 (s), 738 (w), 717 (w), 680 (w); for  $\text{FO}(\text{CF}_2)_5\text{OF}$ : 1348 (sh), 1332 (m), 1258 (sh), 1227 (vs, complex), 1174 (s), 1148 (s), 1110 (m), 1036 (w), 1014 (w), 897 (wm), 877 (wm), 855 (wm), 820 (w), 793 (wm), 778 (wm), 752 (s), 727 (ms), 705 (w), 694 (w); for  $\text{CF}_2(\text{NF}_2)\text{CF}_2\text{OF}$ : 1333 (ms), 1253 (vs), 1218 (vs), 1176 (sh), 1159 (s), 8018 (ms), 977 (s), 936 (s), 893 (wm), 881 (w), 781 (m); and for  $\text{CF}_2\text{CF}(\text{NF}_2)\text{CF}_2\text{OF}$ : 1311 (ms), 1277 (s), 1252 (vs), 1183 (m), 1136 (wm), 1099 (w, complex), 1011 (m), 968 (sh), 963 (m), 932 (m), 984 (wm, complex), 813 (wm), 766 (w), 741 (wm).

The infrared spectra of all the new compounds exhibit multiple bands in the region (1400–1000  $\text{cm}^{-1}$ ) which are assigned to C–F stretching vibrations. They also show several weak-to-medium intensity absorptions in the O–F<sup>2</sup> and C–O<sup>6</sup> domain (917–855  $\text{cm}^{-1}$ ). The difluoroamino derivatives have absorptions between 1020 and 925  $\text{cm}^{-1}$ , and some of these may be assigned to the N–F stretching motions.

**<sup>19</sup>F Nmr Spectra.** The <sup>19</sup>F nmr spectra were obtained on  $\text{CCl}_4\text{F}$  solutions of the fluoroxy derivatives at room temperature employing a Varian Model V4310 spectrometer operating at 40 Mc at room temperature. Resonances for  $\text{FO}(\text{CF}_2)_4\text{OF}$  are located at  $\phi$  –146.7, 92.5, 122.7 having an area ratio of 1.0:2.0:2.1, respectively, while the spectrum of  $\text{FO}(\text{CF}_2)_5\text{OF}$  shows absorptions at  $\phi$  –146.9, 92.9, and 124.0 having the respective area ratio, 1.0:2.1:3.1. 1-Fluoroxy-2-difluoroaminotetrafluoroethane has resonances at  $\phi$  –147.0, –17.3, 92.5, and 115.2; the area ratio was measured to be 1.0:1.8:1.9:1.9, respectively, and  $\text{CF}_2\text{CF}(\text{NF}_2)\text{CF}_2\text{OF}$  has

bands at  $\phi$  -150.7, -24.3, 72.8, 86.1, and 167.2 (area ratio 1.0:1.8:3.1:2.01:1.0, respectively).

The nmr spectra of these compounds are rather diagnostic. They all have resonances near  $\phi$  -150 which are assigned to the fluoroxy fluorine atoms. Both CF<sub>3</sub>(NF<sub>3</sub>)CF<sub>3</sub>OF and CF<sub>3</sub>CF(NF<sub>3</sub>)CF<sub>3</sub>OF have an absorption assigned to the NF<sub>3</sub> group fluorine atoms at -17.3 and -24.3, respectively. The NF<sub>3</sub> group fluorine resonance lies at higher field when the group is bound to a CF<sub>3</sub> than when it is attached to a CF. The positions of these N-F fluorine absorptions are close to those found in the respective  $\alpha$ -difluoraminoacyl fluorides.<sup>6</sup> Other resonances for FO(CF<sub>3</sub>)<sub>2</sub> are located at  $\phi$  92.5 (terminal CF<sub>3</sub>) and 122.9 (central CF<sub>3</sub>); for FO(CF<sub>3</sub>)<sub>2</sub>OF at 92.9 (terminal CF<sub>3</sub> groups) and 124.0 (three central CF<sub>3</sub> groups); for CF<sub>3</sub>(NF<sub>3</sub>)CF<sub>3</sub>OF at 92.5 (CF<sub>3</sub> group adjacent to OF) and 115.2 (CF<sub>3</sub> adjacent to NF<sub>3</sub>); and for CF<sub>3</sub>CF(NF<sub>3</sub>)CF<sub>3</sub>OF at 72.8 (CF<sub>3</sub>), 86.1 (CF<sub>3</sub>), and 167.2 (CF). These tentative assignments are based on field positions, area ratios, and comparison of the spectra of these new compounds with each other as well as with published information.<sup>3,6</sup>

**Alkaline Hydrolysis.** Both FO(CF<sub>3</sub>)<sub>2</sub>OF (52.2 mg) and FO(CF<sub>3</sub>)<sub>2</sub>OF (80.0 mg) were admitted into bulbs containing 50 ml of 0.996 N NaOH solution and allowed to stand at room temperature for 3 hr. The aqueous phases were titrated to determine the amount of hydroxide consumed as well as analyzed for fluoride. The vapor phases were measured by their pressure-volume-temperature relationships and subjected to mass spectral analysis. The analytical results are summarized in Table II.

Table II. Alkaline Hydrolysis

Products, moles/mole of reactant	FO- (CF <sub>3</sub> ) <sub>2</sub> OF	FO- (CF <sub>3</sub> ) <sub>2</sub> OF	Theory
F <sup>-</sup>	5.9	5.7	6.0
O <sub>2</sub>	0.9	0.9	1.0
OH <sup>-</sup> (consumed)	8.7	8.5	8.0

The alkaline hydrolysis of both FO(CF<sub>3</sub>)<sub>2</sub>OF and FO(CF<sub>3</sub>)<sub>2</sub>OF followed the general equation

The presence of trace quantities of perfluorocarbons and the larger than theoretical quantities of OH<sup>-</sup> consumed is explained by the known decarboxylation of perfluorinated acids in alkaline solution.

## Results and Discussion

Cesium fluoride has been shown to catalyze the addition of fluorine across the sulfur-oxygen double bond of thionyl fluoride.<sup>7</sup> It was postulated that the active

intermediate in the fluorination was the SF<sub>6</sub>O<sup>-</sup> ion. Since cesium fluoride was reported to react with carbonyl fluoride to form CsOCF<sub>3</sub>,<sup>8</sup> an attempt was made to determine whether cesium fluoride would catalyze the addition of fluorine across the C=O bond of several fluorocarbon derivatives. This was found to occur readily and high yields of the corresponding fluoroxy compounds could be obtained when the reactions were allowed to progress at -78° in a static system. The following conversions to known compounds were easily accomplished: COF<sub>2</sub> → CF<sub>3</sub>OF, 97% yield; CF<sub>3</sub>COF → C<sub>2</sub>F<sub>5</sub>OF, 96% yield; C<sub>2</sub>F<sub>5</sub>COF → C<sub>3</sub>F<sub>7</sub>OF, 97% yield; and (CF<sub>3</sub>)<sub>2</sub>CO → (CF<sub>3</sub>)<sub>2</sub>CFOF, 98% yield.<sup>1</sup> When the technique was extended to include the two diacyl fluorides derived from perfluorosuccinic and perfluoroglutaric acids, the corresponding bis(fluoroxy) compounds were produced. These reactions were car-

ried out using close to stoichiometric amounts of fluorine in order to eliminate C-C bond cleavage that is commonplace with fluorinations carried out at elevated temperatures. The advantage of this catalyzed method of fluorination becomes obvious in comparing the yield in the preparation of the only other known example of a bis(fluoroxy) compound, FO(CF<sub>3</sub>)<sub>2</sub>OF (approximately 2%),<sup>4</sup> with the yields obtained in this study. The yields of the monofluoroxy derivatives are also much higher than those previously reported, and essentially no purification of the compounds is necessary for most purposes.

The high-temperature fluorination of carbon dioxide has been reported to produce only the known fluoroxy compound, CF<sub>3</sub>OF.<sup>9</sup> However, in the presence of cesium fluoride the catalytic addition of fluorine occurs, and CF<sub>3</sub>(OF)<sub>2</sub> is obtained in nearly quantitative yield. Some variation in the conversion was noted, and this

to depend on the history of the cesium fluoride used. Better results were obtained with a catalyst as been previously used to convert the acid derivatives to fluoroxy compounds. Identification of  $\text{CF}_3(\text{OF})_2$  was achieved by vapor density, molecular weight and by a comparison of its infrared and  $^{19}\text{F}$  nmr spectra with those previously obtained.<sup>10</sup> This method of fluorination could not be extended to compounds containing an atom or group other than carbon or a perfluoroalkyl group bonded to the carbon. Displacement occurred and only the fluoroxy compound derived from the related acid fluorides was observed upon fluorination. For example, reaction of  $\text{COCl}_2$  with 1 equiv of fluorine at  $-78^\circ$  in the presence of  $\text{CsF}$  produced only  $\text{CF}_3\text{OF}$  and chlorine in small amounts. Unreacted  $\text{COCl}_2$  was also recovered. Fluorination of  $\text{FCONF}_2$  with excess fluorine at  $0^\circ$  yielded  $\text{NF}_3$  and  $\text{CF}_3\text{OF}$  as the major products. However, the catalyzed fluorination of the  $\alpha$ -substituted aminoacyl fluorides,  $\text{NF}_2\text{CF}_2\text{C}(\text{O})\text{F}$  and  $\text{CF}_3\text{CF}_2\text{C}(\text{O})\text{F}$ , produced the corresponding fluoroxy compounds in high yield. Both products are stable in

the gas phase in Pyrex at room temperature.

The fluorination of  $\text{HCF}_2\text{COF}$  at  $0^\circ$  produced an unstable material which was contaminated with small amounts of  $\text{COF}_2$ ,  $\text{HCF}_3$ , and  $\text{CF}_4$ . Purification of this material by either vacuum-line fractionation or gas chromatography resulted in spontaneous and often violent decomposition. The main products in this position were  $\text{COF}_2$  and  $\text{HCF}_3$ . The  $^{19}\text{F}$  nmr

of G. Thompson, private communication.

spectrum of the crude product consisted of an unresolved broad singlet at  $\phi -131$  (OF), an unresolved singlet at  $\phi 99.9$  (C-F), and a doublet at  $\phi 136.4$  (C-F) ( $J_{\text{HF}} = 56$  cps). The relative area ratio of the peaks is 1.0:2.1:1.9. This spectrum is consistent with the formulation of the compound as  $\text{HCF}_2\text{CF}_2\text{OF}$ . The infrared spectrum of the crude material showed no absorptions attributable to a carbonyl group but exhibited a weak band in the fluoroxy region which was not observed in the starting material. The instability of this hydrogen-containing fluoroxy compound is in agreement with previous observations.<sup>3,4</sup>

The presence of a metal fluoride is necessary in these reactions although its role is not known with certainty. For example, when either  $\text{CF}_3\text{COF}$  or  $(\text{CF}_3)_2\text{C}=\text{O}$  was allowed to stand with 1 equiv of fluorine at  $-78^\circ$  in a Pyrex reactor, no reaction was observed and the carbonyl derivatives were quantitatively recovered. However, in the presence of an alkali metal fluoride the formation of the corresponding fluoroxy compound was complete in 1 hr (on the 1–2-mmole scale). It is probable that the metal fluoride either reacts directly with or polarizes the carbon-oxygen double bond to such an extent that a polar intermediate is formed, which is the active species in the fluorination. Support for this assumption was obtained by fluorination of  $\text{CsOCF}_3$  at  $-78^\circ$  in a static system. Fluoroxytrifluoromethane was formed in quantitative yield. Furthermore, when  $(\text{CF}_3)_2\text{C}=\text{O}$  was allowed to react with an excess of  $\text{CsF}$ , it was completely absorbed and could not be removed *in vacuo* at ambient temperature. Fluorination of the preabsorbed  $(\text{CF}_3)_2\text{C}=\text{O}$  under similar conditions also produced  $(\text{CF}_3)_2\text{CFOF}$ .

# Spectroscopic Studies of Isotopically Substituted Metal Carbonyls. I. Vibrational Analysis of Metal Pentacarbonyl Halides<sup>1a</sup>

Herbert D. Kaesz, Robert Bau, David Hendrickson,<sup>1b</sup> and J. Michael Smith

Contribution No. 2006 from the Department of Chemistry, University of California, Los Angeles, California 90024. Received December 17, 1966

**Abstract:** All of the infrared absorptions including the many minor peaks hitherto neglected in the spectra of the pentacarbonyl halides  $M(CO)_5X$  ( $M = Mn, Re$ ;  $X = Cl, Br, I$ ) have been assigned to the carbonyl stretching modes of the all-<sup>12</sup>C derivative (95% natural abundance) and the principal monoisotopic species  $M(^{12}CO)_4(^{13}CO)X$  (4% <sup>13</sup>C-*cis* and 1% <sup>13</sup>C-*trans* to  $X$ ). Calculations using an energy-factored block of the ( $FG^{-1}$ ) matrix for the carbonyl stretching modes (but without any other predetermined constraints on the force field) have given all five force constants in the block. These support the proposed assignments and also verify previous models for the force fields in these molecules. The <sup>13</sup>CO absorptions have been experimentally verified through enrichment; axial and radial CO groups are observed to be approximately equally enhanced by <sup>13</sup>CO exchange in disagreement with interpretations of previous radiocarbon tracer studies.

Although the infrared carbonyl stretching absorptions of  $M(CO)_5X$  derivatives have received a great deal of attention,<sup>2-5</sup> certain of their features have not yet been satisfactorily explained. It remains to assign the many minor peaks often attributed<sup>6</sup> but actually never proved to be absorptions of <sup>13</sup>CO-substituted molecules occurring in natural abundance. These, as we will show below, are a source of valuable information. Also, while it is not the subject of the present communication, a quantitative treatment of the intensities<sup>7</sup> is still lacking; the present vibrational analyses provide important information toward our understanding of such data.

In previous analyses of the carbonyl absorptions, only vibrations of the principal species, the all-<sup>12</sup>C molecule (95% abundance in  $M(CO)_5X$  derivatives), have been utilized. Since there are five force constants to be evaluated in the carbonyl block of the secular equation but only four absorptions observed for the principal species, it has been necessary to make several approximations<sup>4</sup> in the force field (see Discussion below). With the additional data from the <sup>13</sup>CO-substituted molecules (experimentally verified here through <sup>13</sup>CO enrichment), a full set of five force constants could be calculated without any assumptions about the force field (other than the usual factoring of the carbonyl stretching block from the lower energy vibrations of the molecules). The use of necessary and sufficient vibrational frequencies to match the number of force constants in a molecule has recently been reported by Lewis, Manning, and Miller<sup>8</sup> for derivatives  $L_2Mn_2(CO)_8$

in which the <sup>13</sup>CO vibrations served as a check on the calculations.

One important consequence of such work is that all the bands of the <sup>13</sup>CO-substituted molecules can be assigned, thus resolving, for the pentacarbonyl hydrides<sup>9</sup> at least, difficulties which had arisen in the assignment of a structure from the carbonyl modes. In addition, the identification of the <sup>13</sup>CO absorptions provides a direct method for following the stereochemistry of CO substitution using <sup>13</sup>C-enriched CO.

## Experimental Section

The compounds  $M(CO)_5X$  ( $M = Mn, Re$ ;  $X = Cl, Br, I$ ) were either available in our laboratory from previous work<sup>10</sup> or with one modification were prepared following published methods.<sup>10,11</sup>  $Re(CO)_5Br$  is obtained in high purity by treating  $Re_2(CO)_{10}$  with  $Br_2$  in cyclohexane at room temperature. Disappearance of starting carbonyl is monitored by infrared spectrum.

<sup>13</sup>C-Enriched  $Mn(CO)_5Br$ . Wojcicki and Basolo<sup>12</sup> found through radioactive tracer studies that CO readily exchanges in solution with  $Mn(CO)_5Br$ . <sup>13</sup>C-Enriched  $Mn(CO)_5Br$  was thus prepared in our laboratories by exchange with 50% <sup>13</sup>C-enriched CO (Merck Sharpe and Dohme, Ltd., Canada). In a typical exchange experiment 4.5 mg of  $Mn(CO)_5Br$  was dissolved in cyclohexane (3 ml) in a small reaction flask fitted with two stopcocks. The total contained volume of the vessel including the stems up to the stopcocks was about 5 ml. One of the stopcock arms was covered with a rubber syringe cap for later withdrawing samples for infrared spectra. The other stopcock was connected to a vacuum line. The solution was thoroughly degassed (through several cycles of cooling to  $-196^\circ$ , pumping, and thawing), and finally at room temperature the 50% <sup>13</sup>C-enriched CO was introduced to a pressure of about 1 atm by mercury displacement from a storage bulb. During the exchange, spectroscopic samples (each 0.3 ml) were removed by syringe through the rubber cap and stopcock. The samples were then flushed free of CO by bubbling purified nitrogen through the liquid for a few minutes (dissolved <sup>13</sup>CO will continue to exchange during the slow, high-resolution infrared scan, distorting the relative intensities of the peaks). After exchange was completed, the <sup>13</sup>CO-depleted gas was separated from cyclohexane and carbonyl derivative and recovered for other uses by means of a Toepler pump and distillation train on the vacuum line.

<sup>a</sup> To allow future checks on our calculations, frequencies are given to a precision of one significant figure beyond our experimental accuracy ( $\pm 1 \text{ cm}^{-1}$ , see text). A typical spectrum is shown in Figure 1, part I. <sup>b</sup> Not observed; calculated from best fit of force constants. <sup>c</sup> Observed in Raman spectrum at 2079.5. <sup>d</sup> Observed in Raman spectrum at 2072.0.

Spectra showing the original solution of  $\text{Mn}(\text{CO})_5\text{Br}$  and subsequent  $^{13}\text{CO}$  enrichment through exchange are given in Figure 1.

**Infrared Spectra. Carbonyl Stretching Region.** The infrared spectra of the region  $1800$  to  $2200 \text{ cm}^{-1}$  were recorded using a Beckman IR-4 spectrophotometer equipped with a  $\text{LiF}$  prism. For

Figure 1. High-resolution infrared spectra in the carbonyl stretching region of  $\text{Mn}(\text{CO})_5\text{Br}$  before and after exchange with  $^{13}\text{CO}$  (50%).

reasons stated in the Discussion below, it was of the utmost importance to obtain the best possible accuracy within each of the observed spectra. These were determined to  $\pm 0.3 \text{ cm}^{-1}$  while the absolute accuracies were about  $\pm 1$  or  $2 \text{ cm}^{-1}$ .

The instrument was run at a scan speed of  $0.025 \mu/\text{min}$  with an expansion of  $6 \text{ in.}/\mu$  on a chart lined every  $0.02 \mu$ . Spectra were calibrated against the  $5.029 \mu$  line of  $\text{H}_2\text{O}$  vapor in the air, with the instrument on single beam. Calibration by this method gave reproducibility of about  $\pm 0.001 \mu$ , or  $0.5 \text{ cm}^{-1}$ , for each measurement. As two measurements are involved in each frequency, i.e., the frequency itself and the calibration peak, the accuracy is thus roughly  $\pm 1 \text{ cm}^{-1}$ . The spectrum of each compound was measured several times, and the average value of up to six spectra is presented

here. The measurement of peak differences for several spectra gave a reproducibility to about  $\pm 0.3 \text{ cm}^{-1}$ . The data are presented in Table I.

Samples were dissolved in cyclohexane (for the optimum resolution), and spectra were taken at various concentrations, including solutions supersaturated by warming to bring out the  $^{13}\text{CO}$  absorptions in natural abundance;  $\text{CaF}_2$  sample cells were used of 1-mm thickness, the maximum possible path length without having solvent absorptions destroy instrument response. With warmed solutions, the sample cells had to be heated also, to prevent recrystallization in the cell. This was most conveniently accomplished by placing the cells in the beam of the instrument for about an hour before they were used. Heating causes decomposition of most of the derivatives studied, and it was necessary to subtract the peaks due to decomposition products (essentially the tetracarbonyl halide dimers). Such peaks have been accurately measured before<sup>14</sup> and are identified both by their position on calibrated spectra as well as their behavior after different periods of heating.

**Raman Spectra. Carbonyl Stretching Region.** Raman spectra for several of these derivatives were attempted on the laser-source Cary 81, made available to us at the Applied Physics Corp. (now Cary Instruments, a Varian subsidiary) in Monrovia, Calif. The most intense band is the Raman-active  $B_1$  mode, for  $\text{Mn}(\text{CO})_5\text{Br}$  at  $2079.5$  and  $\text{Mn}(\text{CO})_5\text{I}$  at  $2072 \text{ cm}^{-1}$ . Several other weaker Raman shifts were also seen, corresponding to the Raman-infrared active modes which had previously been measured in the infrared so these provided no new information. In addition, Raman shifts attributable to decomposition products were also seen.

**Overtone and Combination Region.** The infrared spectra in the region  $3800$  to  $4300 \text{ cm}^{-1}$  were measured for one representative  $M(\text{CO})_5\text{X}$  derivative, namely  $\text{Mn}(\text{CO})_5\text{Br}$ , for which a more extensive vibrational analysis was carried out. The data were collected on a Cary 14 spectrophotometer; the overtone and combination absorptions are an order of magnitude weaker than the fundamentals. Carbon tetrachloride was used as a solvent because of its transparency in this region. The sample was warmed to give a supersaturated solution, which was placed in 10-cm path length quartz cells which had been prewarmed and left wet with solvent. Decomposition bands, if any, were identified as described above. The spectrum, typical of the  $M(\text{CO})_5\text{X}$  derivatives, is shown in Figure 2. The maxima identified for this work are indicated by

Figure 2. Overtone and combination spectrum,  $\text{Mn}(\text{CO})_5\text{Br}$ . The vertical lines below the maxima indicate our assignments; these are intended also to reflect somewhat the relative intensities of the bands.

(13) M. A. El-Sayed and H. D. Kaesz, *Inorg. Chem.*, **2**, 158 (1965).

ons in proportion to the abundance of the individual species and the extinction coefficients of the bands, some of which (but not all) will be distinguishable from the spectrum of the parent all- $^{12}\text{C}$  molecule.

$^{13}\text{C}$  substitution in the axial position, the symmetry of the resultant molecule is the same as that of the parent all- $^{12}\text{C}$  molecule (since the position of substitution lies on all elements of symmetry for the molecule). Therefore the symmetry coordinates are the same for these two molecular species. A lower frequency is expected for any vibration involving motion of the heavier  $^{13}\text{C}$ , and no shift in frequency is expected for the modes that do not involve  $^{13}\text{C}$ . Thus the  $B_1$  modes will be the same for the parent and axial-substituted molecules. Also, if the two  $A_1$  modes were pure radial and pure axial vibrations, only the axial  $A_1$  mode would be shifted. However, they are not, and both are observed to shift but not necessarily by the same amount. The sum of these shifts very nearly equals the expected  $45\text{ cm}^{-1}$  for isotopic mass shift. The amount of shift of each mode will be proportional to the amount of axial CO motion in the modes. For the present we are satisfied to assign only band h to this mode, as the  $A_1$  (axial) vibration.

For radial  $^{13}\text{C}$  substitution, the symmetry is lowered, and the symmetry coordinates must be written differently as shown in Figure 5. In this case one of the vibrations, the  $A''$ , corresponds to one of the parent molecule vibrations, the E mode. Four vibrations belong to the same symmetry class, and these are expected to be mixed; any or all of our  $A'$  vibrations are expected to occur at frequencies different from the vibrations of the parent  $\text{C}_4\text{v}$  molecule, with the expected full  $^{13}\text{C}$  isotopic shift of  $45\text{ cm}^{-1}$  distributed among the shifts of the four vibrations according to the Teller-Redlich product rule (meaning, of course, the modes outside the carbonyl group). To a first approximation, therefore, vibrations are expected to occur at frequencies slightly lower than any corresponding vibrations in the parent molecule.

Also one might guess at this point that the shift of the  $A'$  vibration of the  $\text{C}_4\text{v}$  molecule corresponding to the symmetry coordinate of the axial  $A_1$  mode of the parent molecule will be fairly small.

Because of its position relative to the E mode (band f of the parent molecule, band f is assigned as an  $A'$  mode of the radial mono- $^{13}\text{C}$  molecule. The most probable one of the four possible  $A'$  modes to assign a frequency to (guided by the symmetry coordinates) is the third highest  $A'$  vibration of the  $\text{C}_4\text{v}$  molecule, corresponding in relative motions of CO groups to the mode in the all- $^{12}\text{C}$  derivative.

Bands c and b could be assigned either to the radial  $A_1$  mode of the  $\text{C}_{4v}$   $^{13}\text{C}$ -substituted molecule or to the first  $A'$  of the  $\text{C}_1$  molecule. The latter assignment is preferred on the basis that its intensity is nearly 10% of the parent radial  $A_1$  vibration. It is expected that the radial  $A_1$  vibration of the  $\text{C}_{4v}$  mono- $^{13}\text{C}$  molecule would be about 1% the intensity of the parent radial  $A_1$  vibration while  $A'$  of the  $\text{C}_1$ -substituted molecule would be expected to gain intensity due to its probable asymmetry about the former  $\text{C}_4$  axis. This assignment is supported by the fact that no other vibration is observed below the parent radial  $A_1$  which might correspond to the  $A'$  of the  $\text{C}_{4v}$   $^{13}\text{C}$  axial-substituted molecule.

Figure 5. Symmetry coordinates for mono- $^{13}\text{C}$ O (radial)  $\text{M}(\text{CO})_4\text{X}$ .

The assignment of the remaining two frequencies, bands c and d, are not obvious. These will be determined through calculation of force constants which will also provide a check for the previously mentioned assignments.

**Confirmation and Completion of the Assignments through Calculation of Force Constants.** The above assignments and a set of approximate starting force constants are adjusted by an iterative computer program (see Experimental Section) to fit the frequencies of the all- $^{12}\text{C}$ O and the mono- $^{13}\text{C}$ O axial and radial substituted  $\text{M}(\text{CO})_4\text{X}$  for a given M and X. For a given derivative (i.e., given M and X), we expect that the force constants for the  $^{13}\text{C}$ -substituted molecules will essentially be the same as for the all- $^{12}\text{C}$  derivative. This has been shown to be true for the isotopic substitution of deuterium for hydrogen, involving a 100% increase in weight, and will certainly hold for the  $^{13}\text{C}$ - $^{12}\text{C}$  substitution. The additional information supplied by the  $^{13}\text{C}$ O frequencies appears as new frequency parameters ( $\lambda$ 's) in the secular equation  $|\text{GF} - \lambda\text{E}| = 0$ .

Because not all of the observed frequencies are independent, the calculations require a greater number of input frequencies than there are force constants to be determined. There are eight observed frequencies, a-h (see Figure 1 and Table I), from which six frequencies are needed to determine the five force constants in the carbonyl stretching block. The bands a, e, g, h, f, and b (in order of their appearance in the discussion of band assignments above) were selected as input data, and, also, a set of starting force constants is supplied to the computer program. In the present case, it is found that the approximate force constants of Cotton and Kraihanzel<sup>4</sup> ( $K_1$ ,  $K_2$ , and  $K_3$  which is equal to  $K_c$  and  $K_c'$  and  $1/2 K_3$ ) provide a suitable starting point since they are quite close to the final values. Even in those cases where starting force constants are not close to the final values, the program is able, through a larger number of iterations, to arrive at the optimum answers.

The optimum calculated force constants and the associated frequencies for all the modes are shown in Table III for a model compound,  $\text{Mn}(\text{CO})_5\text{Br}$ . The calculated frequencies for bands a, e, g, h, f, and b fit to within  $0.1\text{ cm}^{-1}$  of the values used as input. This is a good sign that the input frequencies were placed in their proper assigned positions. The calculation of the two remaining observed frequencies, not used as input, also serves as an independent check on the correctness of the assignments. Bands c and d are predicted within  $3\text{ cm}^{-1}$ , the range of expected error derived from using frequencies uncorrected for anharmonicity. A different set of six input frequencies, using either one or both of bands c and d, but dropping one or two of the previous input frequencies, would produce calculated force constants to within  $0.02\text{ mdyne/\AA}$  of these reported values, and again predict the remaining two frequencies within the same range of error ( $3\text{ cm}^{-1}$ ).

**Table III.** Calculation of Force Constants to Assign Bands c and d in  $\text{Mn}(\text{CO})_5\text{Br}$ 

Molecule (symmetry)	Vibr	Input, $\text{cm}^{-1}$	Calcd, $\text{cm}^{-1}$	Obsd, $\text{cm}^{-1}$	Band designation

Force constants, mdynes/A		$K_1 = 16.35$ $K_2 = 17.41$	$K_3 = 0.186$ $K_4 = 0.305$	$K_5 = 0.432$	

\* Observed in Raman at 2079.5 (strong); very weak in the infrared.  
 † Buried beneath 2134.0 (band a). ‡ Coincides with  $\text{B}_1$  of  $\text{Mn}(\text{CO})_5\text{Br}$ . § Coincides with E of  $\text{Mn}(\text{CO})_5\text{Br}$ . ¶ Buried beneath 2000.8 (band g).

It should be noted that the  $\text{B}_1$  vibration is expected in the Raman spectrum although a very weak band in the infrared spectrum (band c) is observed in the calculated position. With the laser Raman, the strongly active  $\text{B}_1$  was observed for  $\text{Mn}(\text{CO})_5\text{Br}$ , the value coinciding with the weak infrared band c. At the high concentrations needed to see all the minor isotopic peaks, we expect to see some weak absorptions not normally predicted in the infrared, which effect has been observed for solutions of  $\text{Mo}(\text{CO})_6$  in  $\text{CCl}_4$ .<sup>18</sup>

Not all of the vibrations predicted for the  $^{13}\text{C}$  molecules can be separately observed in the mixture occurring in natural abundance. The presence of an axial mono- $^{13}\text{CO}$  derivative ( $\text{C}_{4v}$  symmetry) is detected by only one nonoverlapping band, h. As indicated in Table III and in the previous discussion, the  $\text{B}_1$  and E bands of this derivative are expected to coincide with the corresponding modes of the all- $^{12}\text{CO}$  molecule and therefore are masked by its more intense absorptions. Similarly, the high-energy  $\text{A}_1$  mode through its coupling with the axial mode of the same symmetry is slightly shifted from the high-energy  $\text{A}_1$  mode of all- $^{12}\text{CO}$  derivative, but apparently not enough to allow resolution of this peak, more difficult due to its lower relative intensity. The radial mono- $^{13}\text{CO}$  derivative ( $\text{C}_s$  symmetry) on the other hand shows three separate bands through which it may be characterized, all from the  $\text{A}'$  block. The  $\text{A}''$  of this derivative is expected to coincide with the E mode of the all- $^{12}\text{CO}$  molecule. These characteristic bands for the mono- $^{13}\text{CO}$  substituted molecules will be useful later in following stereochemistry of  $^{13}\text{CO}$  substitution in enrichment experiments, through which these  $^{13}\text{CO}$  assignments have also been confirmed (see below).

The assignments and calculated force constants may conveniently be summarized by energy-splitting diagrams shown in Figure 6. Through such a graphic representation, formally analogous to spin-spin splitting diagrams in nuclear magnetic resonance analyses, it

(18) L. H. Jones, *J. Chem. Phys.*, **36**, 2375 (1962).

is possible at a glance to understand several features of the vibrational analysis.

In the first row of each of the three frames in the figure (one for each of the compounds illustrated), the energy of the hypothetically isolated internal coordinate is represented by a vertical dashed line. This is the position obtained from the calculated force constants,  $K_1$  and  $K_2$ , by the equation  $\nu_1^2 = (5.888 \times 10^{-7})K_1/\mu$  (where  $\mu$  is the reduced mass of the carbonyl group in atomic weight units  $(16.00 + 12.01)/(16.00 \times 12.01) = 0.14583$ .) The energy (in  $\text{cm}^{-1}$ ) is plotted on the horizontal axis.

The second row represents symmetry coordinates which are constructed from the internal coordinates.<sup>19</sup> The energies of these are calculated from the interaction constants according to the secular equations for each symmetry coordinate. The third row represents the "normal" coordinates which are the final results of the iterative computation. In these, the positions of the E and  $\text{B}_1$  or  $\text{A}''$  modes are unchanged from the second line. However, the positions of the  $\text{A}_1$  or  $\text{A}'$  coordinates are altered in proportion to the mixing between the symmetry coordinates. The final observed spectrum of  $\text{Mn}(\text{CO})_5\text{Br}$  with  $^{13}\text{C}$  isotopically substituted molecules in natural abundance is composed of the sum of the third lines from each of the frames, at a relative intensity determined by the absolute intensity of the band multiplied by its isotopic abundance.

The force constants calculated for the other members of the  $\text{M}(\text{CO})_5\text{X}$  series are given in Table IV. These proceed entirely analogously to the assignments and calculations discussed in detail for  $\text{Mn}(\text{CO})_5\text{Br}$ .

**Table IV.** Calculated Carbonyl Force Constants for  $\text{M}(\text{CO})_5\text{X}$  Molecules\*

M	$\text{M}(\text{CO})_5\text{X}$ X	mdynes/A				
		$K_1$	$K_2$	$K_3$	$K_4$	$K_5$

Re	I	16.11	17.39	0.292	0.254	0.551

\* For the possible absolute accuracy of these force constants see the Discussion in the text.

**Physical Significance and Trends in the Calculated Force Constants.** The possible accuracy of the force constants derived from the energy-factored vibrational analysis has been discussed previously.<sup>8,20</sup> A full normal coordinate analysis would require the imposition of some force field on the molecule as less data are now available than force constants to be evaluated. As such, this would provide no real check on the energy-factored force constants. Any differences observed between those two sets of force constants would reflect the differences between the assumed force field and the procedure

(19) For derivatives of  $\text{C}_{4v}$  symmetry, the positions are given by the equations:  $\nu_1^2$  (radial) =  $5.888 \times 10^{-7}(K_2 + 2K_3 + K_4)/\mu$ ;  $\nu_2^2$  =  $5.888 \times 10^{-7}(K_2 - 2K_3 + K_4)/\mu$ ;  $\nu_3^2$  =  $5.888 \times 10^{-7}(K_2 - K_4)/\mu$ . For derivatives of different symmetry, these equations may be written following standard procedures; see E. B. Wilson, J. C. Decius, and P. C. Cross "Molecular Vibrations," McGraw-Hill Book Co., Inc., New York, N. Y., 1955.

(20) F. A. Cotton, *Inorg. Chem.*, **3**, 702 (1964).

Figure 6. Energy-splitting diagrams for  $\text{Mn}(\text{CO})_5\text{Br}$ , all- $^{12}\text{CO}$  (95% natural abundance), and the principal monoisotopic species  $\text{Mn}(^{13}\text{CO})_4(^{12}\text{CO})\text{Br}$ , (4%  $^{13}\text{CO}$ -cis and 1%  $^{13}\text{CO}$ -trans to Br).

of energy factoring (which in itself is a force field of one kind).

The match to the  $^{13}\text{CO}$  vibrations observed in the present and the previous work<sup>8</sup> provides one measure of confidence in the procedure of energy factoring. Previous normal coordinate analyses of carbon derivatives<sup>21,22</sup> further show (from the potential energy distribution) that the CO stretching modes are relatively unmixed. An additional test of the energy-factoring procedure was possible in the pentacarbonyl hydrides.<sup>9</sup> In these derivatives, the carbonyl stretching force constants were calculated both omitting and including the metal-hydrogen stretching frequencies lying nearby

(ca.  $1800\text{ cm}^{-1}$ ). Only small changes were produced in the force constants, giving us some additional measure of confidence that changes brought about by inclusion of the next-nearest vibrations (metal-carbon stretching and metal-carbonyl deformation modes, near  $600\text{ cm}^{-1}$ ) would be even smaller (assuming that the coupling constants in these vibrations with the carbonyl stretching modes are of the same order of magnitude as those for the metal-hydrogen stretching modes with these vibrations).

The present force constants show that the valence force field proposed by Jones<sup>18,23</sup> (namely that  $K_c = K_c' = 1/2 K_t$  is approximately correct. However, a further degree of refinement is now available which will be useful in any future attempts at a full normal coordinate analysis.

Figure 7. Calculated frequencies for all possible  $^{13}\text{CO}$ -substituted  $\text{Mn}(\text{CO})_5\text{Br}$ . The position of  $^{13}\text{CO}$  substitution on the  $\text{M}(\text{CO})_5$  skeleton is indicated by a heavy black dot.

Some interesting trends might be pointed out in these force constants (Table IV). Generally the interaction force constants between carbonyl groups are the largest for the least electronegative and least  $\pi$ -electron-withdrawing substituent ( $\text{X} = \text{CH}_3$ ). The interaction force constants should be closely related to the electron density around the metal in the  $\pi$ -electron model for the coupling of carbonyl modes. Other trends are observed, but these fall within about 10 or 15% of the absolute values of these force constants. We refrain from drawing any conclusions about these more refined variations until we feel sure these are due to inherent properties of the molecules in question rather than possible artifacts of the analytical procedure used here.

**Mixing of the  $A_1$  Symmetry Coordinates in the  $A_1$  Modes and Correlation with Intensities.** The distribution of the  $A_1$  symmetry coordinates (radial and axial) in the high-energy  $A_1$  absorption of all- $^{13}\text{CO}$  and the mono- $^{13}\text{CO}$  axial derivatives is given in Table V. The

Table V. Distribution of Potential Energy of  $A_1$  Carbonyl Stretching Vibrations of the All- $^{13}\text{CO}$  and Mono- $^{13}\text{CO}$  Axial  $\text{M}(\text{CO})_5\text{X}$  Derivatives

<sup>a</sup> This mode is often referred to as the  $A_1$  (radial). For the coefficients of the low-energy  $A_1$  mode ( $A_1$  (axial)), reverse the coefficients under the headings.

coefficients for the pentacarbonyl hydrides (discussed in the subsequent paper)<sup>9</sup> are also included here for comparison. It is seen that the high-energy  $A_1$  mode is by and large a mode of the radial carbonyls, as has been deduced in previous qualitative analyses. Increased contributions of axial motion is observed in the series  $\text{Cl} < \text{Br} < \text{I} < \text{CH}_3$  and D. Within the halogen derivatives, this follows observed increased relative intensity for the high-energy  $A_1$  mode. However, the

position of  $\text{M}(\text{CO})_5\text{D}$  is quite anomalous. These derivatives (and the corresponding hydrides) show the relatively weakest high-energy  $A_1$  absorption. Clearly some effect must be largely responsible for the intensity of the high-energy  $A_1$  mode other than mixing of radial and axial modes. This is currently under study.<sup>7b</sup>

**$^{13}\text{CO}$  Enrichment.** The assignment of bands discussed above makes it possible to distinguish between molecules which have  $^{13}\text{CO}$  located in axial or radial positions. The infrared spectrum is thus a powerful method for following the stereochemical course of reactions involving addition or substitution using  $^{13}\text{C}$ -enriched CO. Stereospecific  $^{13}\text{CO}$  labeling of  $\text{Re}_2(\text{CO})_{10}$  has thus been recently reported.<sup>23</sup>

The exchange of radioactive ( $^{14}\text{C}$ ) labeled CO with pentacarbonyl halide molecules has been studied by Wojcicki and Basolo<sup>12</sup> and Hieber and Wollmann.<sup>14</sup> The kinetic data indicated that four CO groups (the radial CO's) exchanged faster than the fifth group (the axial CO). Wojcicki and Basolo assumed that after exchange of the four labile CO groups was essentially complete (in toluene, in the dark, at  $32^\circ$ ), the fifth CO equilibrated in about 3 hr at  $50^\circ$ . The results of our exchange reactions are shown in Figure 1. After 3 hr, at room temperature, we observed the trace shown in the middle of the figure (light was not excluded from these samples). It is clear that bands f and h, characteristic of the radial and axial mono- $^{13}\text{CO}$ -substituted species, correspondingly, are enhanced at approximately the same rate, as near as we can tell from the present only qualitative knowledge of the extinction coefficients of these two bands. Therefore, it is clear that if the exchange reactions can be interpreted in terms of preferential substitution first into the radial position, this preference appears very minor.

A difference in the solvents used exists, but it is doubtful whether this has any great influence (cyclohexane in our experiments, used to obtain optimum resolution of the infrared bands, while the previous workers used benzene or toluene).

In other experiments, for which the spectra are not shown here, we took special precautions to exclude stray light in our exchange reactions since the previous work was carried out in the dark. Our exchange reactions were also run in the dark, and special precautions were taken during the infrared scan to minimize exposure to radiation. The infrared cell containing the sample was placed *inside* the infrared instrument just before the exit slits, so that only the infrared radiation which had been monochromated through the prism was allowed to pass through the sample. The instrument was run on single beam, and the spectrum was analyzed by subtracting out the weak solvent absorptions in this region. Dark reactions produced the same enrichment as observed in the previously described runs.

With time, more than one  $^{13}\text{CO}$  are expected to exchange into the molecule, and the infrared spectrum will eventually show peaks from molecules with two and more  $^{13}\text{CO}$ 's (lower traces, Figure 1). The calculated force constants for the parent molecule enable us to calculate the expected frequencies for all possible  $^{13}\text{CO}$  substitution products. The results of this calculation

(23) R. W. Harrill and H. D. Kaesz, *Inorg. Nucl. Chem. Letters*, **2**, 69 (1966).

(24) W. Hieber and K. Wollmann, *Chem. Ber.*, **95**, 1552 (1962).

are shown in Figure 7. The progressive shifts with increasing  $^{13}\text{C}$ O substitution are evident, eventually resulting in a spectrum resembling in every way that of the all- $^{12}\text{C}$ O molecule, but completely shifted to lower energy for the all- $^{13}\text{C}$ O molecule. The 100%  $^{13}\text{C}$ O-substituted molecule was not achieved in this work to any significant extent due to availability of only 50%  $^{13}\text{C}$ -enriched CO. The spectra of intermediate species show some regions of overlap of peaks but at least some peaks which are essentially unobscured and may be used as

characteristic absorptions for the identification of the particular species in question.

**Acknowledgment.** We wish to thank the Applied Physics Corporation (now Cary Instruments, a Varian subsidiary) in Monrovia, Calif., for making available to us the laser-source Cary 18 Raman spectrophotometer. We also acknowledge the UCLA Computation Facility for making available intramurally supported computer time, and Miss Karen Mehner for preparation of the figures.

## Spectroscopic Studies of Isotopically Substituted Metal Carbonyls. II. Assignment of Carbonyl Stretching Absorptions and Their Interaction with Metal-Hydrogen Stretching Modes in Pentacarbonyl Hydrides<sup>1</sup>

P. S. Braterman, R. W. Harrill, and H. D. Kaesz

Contribution No. 2007 from the Department of Chemistry, University of California, Los Angeles, California 90024. Received December 17, 1966

**Abstract:** The infrared absorptions for  $\text{Mn}(\text{CO})_5\text{H}$ ,  $\text{Mn}(\text{CO})_5\text{D}$ ,  $\text{Re}(\text{CO})_5\text{H}$ , and  $\text{Re}(\text{CO})_5\text{D}$  have been recorded in the region 1900–2200  $\text{cm}^{-1}$ . All of the observed maxima are accounted for through assignment to the carbonyl stretching modes of the major constituent,  $\text{HM}(\text{CO})_5$ , and of the principal isotopic species in natural abundance,  $\text{HM}(\text{CO})_5^{13}\text{CO}$ , 4%  $^{13}\text{CO}$  *cis*, and 1%  $^{13}\text{CO}$  *trans* to hydrogen. Calculations of force constants in the energy-factored carbonyl stretching block of the ( $FG^{-1}$ ) matrix support these assignments. The  $^{13}\text{C}$ O absorptions have been experimentally verified through enrichment; axial and radial CO groups are observed to be approximately equally enhanced by  $^{13}\text{C}$ O exchange, in agreement with previous radiocarbon tracer studies. A shift in some of the CO absorptions in going from  $\text{HRe}(\text{CO})_5$  to  $\text{DRe}(\text{CO})_5$  has been observed. This is due to coupling between Re–H and *trans*-CO group stretching vibrations. An interaction force constant has been calculated by including the Re–H stretching vibration in the energy-factored ( $FG^{-1}$ ) matrix. These calculations also provide an interesting check on the method of energy-factored vibrational analysis.

Early spectroscopic studies of the pentacarbonyl hydrides of manganese<sup>2</sup> and rhenium<sup>3</sup> were based on the assumption (derived from earlier electron diffraction work)<sup>4a</sup> that the hydrogen in these compounds did not occupy a position on the coordination sphere of the metal. Subsequent structural determinations on more stable molecular hydrides such as  $\text{HPtBr}(\text{PEt}_3)_4$ <sup>4b</sup> and  $\text{HOsBr}(\text{CO})(\text{PPh}_3)_4$ <sup>4c</sup> revealed that the hydrogen must in fact be counted into the coordination number of the metal like other ligands. At this time, the spectra of the pentacarbonyl halides, especially the extremely low intensity of one of the fundamentals,  $A_1$  (radial), was under study in these laboratories.<sup>5</sup> The realization that the halides and the hydrides might possess related geometry suggested a similar approach to the assignment of spectra in these two series of molecules.<sup>6a</sup>

We concluded that the spectra of the hydrides were consistent with an octahedral model in which hydrogen occupied a coordination position around the metal in the hydrides<sup>6a,b</sup> like the halogens in the halides. This was formally proposed<sup>6a</sup> shortly before the crystal structure of  $\text{HMn}(\text{CO})_5$  was reported.<sup>7a</sup>

We now wish to report complete assignment of carbonyl modes of all the principal species occurring in natural abundance in the pentacarbonyl hydrides: 95% all- $^{12}\text{C}$ O, 4% mono- $^{13}\text{C}$ O radial, 1% mono- $^{13}\text{C}$ O axial. All the absorptions in the spectra of the pentacarbonyl hydrides are thus accounted for, which had confused the earlier infrared structure assignments for these derivatives. The  $^{13}\text{C}$ O modes have been experimentally verified through exchange with  $^{13}\text{C}$ -enriched CO.

To confirm the previously assigned metal-hydrogen stretching absorptions,<sup>2a,3</sup> we have also repeated the spectra of  $\text{DMn}(\text{CO})_5$  and  $\text{DRe}(\text{CO})_5$ . In addition to the large shift in the M–H stretching absorptions, we

\* See Figure 1 for identification of these bands according to designated letters. To allow future checks on our calculations, frequencies are given to a precision of one significant figure beyond our actual experimental accuracy ( $\pm 1 \text{ cm}^{-1}$ ). <sup>b</sup> This band is assigned as the Raman-active  $B_2$  band; it appears as a weak band in only the most concentrated solutions; it has been observed directly by laser-excitation Raman of the neat liquids by A. Davison and J. W. Faller, Massachusetts Institute of Technology, private communication:  $\text{HMn}(\text{CO})_5$ , 2047, and  $\text{HRe}(\text{CO})_5$ , 2055  $\text{cm}^{-1}$ .

observed for  $\text{DRe}(\text{CO})_5$  for the first time<sup>8,9</sup> distinct shifts in at least two of the absorptions in the carbonyl stretching region which were not reported by previous workers. These shifts permit unambiguous assignment of these carbonyl bands to  $A_1$  modes, the same symmetry species as the M-H stretching vibrations with which these have apparently become mixed.

### Experimental Section

**Preparation.** The pentacarbonyl hydrides and deuterides were prepared by methods previously reported for these derivatives.<sup>10</sup> Some additional details only need be mentioned here. The parent carbonyls,  $\text{Mn}(\text{CO})_5$  and  $\text{Re}(\text{CO})_5$ , were purchased from Alfa Inorganics, Beverly, Mass. After reduction of the carbonyls by sodium amalgam in tetrahydrofuran, we found, as others did before, that it is exceedingly difficult to obtain the dry salts necessary in

order to get spectroscopically pure hydride derivatives in the acidification step. The impurities in the sticky solids remaining after reduction and 2 days of pumping under high vacuum up to  $50^\circ$  are extracted with cyclohexane which leaves, after drying under reduced pressure, a slightly colored powder as the pentacarbonyl salt.

The salt is treated under high vacuum with phosphoric acid which has previously been purged with purified nitrogen for several days and then degassed. The volatile products from the acidification are distilled into a trap containing  $\text{P}_2\text{O}_5$  and cooled to  $-196^\circ$ . After completion of the reaction, cyclohexane is distilled into the trap and further purification of the hydride is accomplished by distilling the solution onto fresh quantities of  $\text{P}_2\text{O}_5$  until complete dryness is attained.

The deuterides are prepared using  $\text{D}_2\text{PO}_4$  in the acidification step. However, care must be taken with the vacuum line as the hydrides will exchange rapidly with any protonic sites on the glassware not removed even by pumping at  $10^{-4}$  mm for prolonged periods. Such equipment may be properly conditioned for this work by exposure to  $\text{D}_2\text{O}$  vapor before exposure to any deuteriometal pentacarbonyls.

The yields of  $\text{HRe}(\text{CO})_5$  (about 30%) are much lower than for  $\text{HMn}(\text{CO})_5$  (about 85%). For preparation of hydride sufficient to give the infrared spectra reported here, it was necessary to start with 2.0 g of  $\text{NaRe}(\text{CO})_5$  but only with 0.5 g of  $\text{NaMn}(\text{CO})_5$ .

A great deal of the rhenium may be found in the product mixture in the form of polynuclear carbonyl hydrides of low volatility, described elsewhere.<sup>8,11</sup>

**Exchange Reactions and Infrared Spectra.** The procedures have been described in the accompanying publication.<sup>12</sup> The spectra for  $\text{HRe}(\text{CO})_5$  at two concentrations are shown in upper spectrum of Figure 1. The absorptions after 24-hr exchange with  $^{13}\text{C}$ -enriched CO are shown on the lower spectrum. The positions of the maxima as labeled in the figure are given in Table I.

The spectrum of  $\text{DRe}(\text{CO})_5$  in the region  $1900\text{--}2200 \text{ cm}^{-1}$  is shown in Figure 2. The vertical dashed lines indicate the position of band f and its  $^{13}\text{CO}$  satellite band h in  $\text{HRe}(\text{CO})_5$ , some of which is present in the sample due to imperfect isotopic conversion. The shifts for the two bands f and h are the only perceptible changes in the carbonyl stretching region on going from  $\text{HRe}(\text{CO})_5$  to  $\text{DRe}(\text{CO})_5$ . No such observable shifts are found for the manganese derivatives. These shifts, if any, must be within the range of experimental error which is  $1 \text{ cm}^{-1}$  under our present method of operation. The presence of some residual amount of  $\text{HRe}(\text{CO})_5$  in the  $\text{DRe}(\text{CO})_5$ , shown in Figure 2, is due to exchange of deuteride with traces of water in the apparatus which was used to handle the cyclohexane solution of  $\text{DRe}(\text{CO})_5$ . The last traces of  $\text{HRe}(\text{CO})_5$  may be removed by shaking the cyclohexane solution with oxygen-free  $\text{D}_2\text{O}$ . Conversely, the  $\text{HRe}(\text{CO})_5$  may be regenerated simply by shaking the cyclohexane solution with oxygen-free  $\text{H}_2\text{O}$ . Exchange even in such a heterogeneous system is remarkably rapid.

The metal-hydrogen stretching frequencies, although previously reported,<sup>8,9</sup> have been checked for internal consistency with our present data. The most concentrated solutions of the appropriate derivatives in cyclohexane were scanned with Perkin-Elmer 421 (grating) spectrophotometer. The observed frequencies were found to be as follows:  $\nu_{\text{MnH}} 1775$ ,  $\nu_{\text{MnD}} 1285$ ,  $\nu_{\text{ReH}} 1882$ ,  $\nu_{\text{ReD}} 1313 \text{ cm}^{-1}$ .

**Calculations.** Force constants and "normal" modes were calculated using the iterative computer program of Schachtschneider and Snyder<sup>13</sup> described in the accompanying communication.<sup>12</sup> Calcu-

### Assignment

**Assignment of Absorptions.** The three fundamentals  $A_1$ ,  $E$  for  $\text{HM}(\text{CO})_5$  are chosen according to modes described in the previous work on the pentamethyl halides.<sup>1b</sup> The most intense band, e, will not be the E mode. For the two  $A_1$  modes we choose the weak band at highest energy, a, and a band of medium intensity at lower energy, band f. The assignment of band f as an  $A_1$  species is supported by its odd shift upon deuteration in  $\text{DRe}(\text{CO})_5$ .<sup>9</sup> Only a band of the same symmetry species as the metal-oxygen stretching modes (which must be of  $A_1$  symmetry) could be affected upon deuteration. No perceptible shift in the position of band a is observed in  $\text{CO}_5$ , presumably because this band is less mixed with the Re-H stretching absorption than is band f. The discrimination in the interactions of metal deuterium with certain carbonyl stretching modes has been reported by Vaska.<sup>9</sup>

There are indications that the weak band at  $\sim 2044$  cm<sup>-1</sup>, band c in  $\text{HMn}(\text{CO})_5$ , might be the Raman-active mode for the  $C_{4v}$  molecule. A previous calculation<sup>10</sup> using the approximate secular equations of Wilson and Kraihanzel indicated that the  $B_1$  mode of the derivative might be expected somewhere in this region (calculated position, 2046 cm<sup>-1</sup>). This band gains intensity in the infrared from some breaking of the  $C_{4v}$  symmetry in solution by asymmetric binding of molecules, as suggested by earlier workers in a similar situation for  $\text{Mo}(\text{CO})_6$ .<sup>15b</sup> The calculations indicate that the best fit is obtained when this band is indeed attributed to the Raman mode which is finally proved by the failure of this band to increase in intensity during <sup>13</sup>CO enrichment (see below).

The remaining weak bands may be assigned to either of the two isotopically substituted species in natural abundance containing one <sup>13</sup>CO group, similar to methylenetetrahydrofuran previously.<sup>1b</sup> For the axially <sup>13</sup>CO-substituted molecule, the E and  $B_1$  but not the  $A_1$  modes are identical with those for the all-<sup>12</sup>CO molecule. Assign band h as the  $A_1$  (axial) <sup>13</sup>CO mode, which is shifted by 38 cm<sup>-1</sup> to lower energy from the corresponding <sup>12</sup>CO band (f). This is less than the full isotopic shift of 45 cm<sup>-1</sup> (or more for frequencies uncorrected for anharmonicity).<sup>14</sup> We may thus infer that this band is mixed with one (or more) other mode of the  $C_{4v}$  symmetry ( $A_1$ ). The most likely are the  $A_1$  (axial) carbonyl and the  $A_1$  M-H stretching modes. We therefore expect a band slightly shifted to lower energy from band a (the  $A_1$  (radial) band of the all-<sup>12</sup>CO molecule). It is tempting to assign band b as the  $A_1$  (axial) mode for the <sup>13</sup>CO-substituted  $C_{4v}$  derivative, in fact, such a trial assignment gave a poorer fit to the computer in favor of a band even closer to band a than band b (as discussed below). Such a band has not been resolved by us. It must be pointed out

Figure 2. High-resolution infrared absorptions in the carbonyl stretching region for  $\text{DRe}(\text{CO})_5$ , with some  $\text{HRe}(\text{CO})_5$  present in small quantity as impurity (distinguishing peaks marked with dashed vertical lines).

that such a band, belonging to a very weak absorption of a molecule present only in 1% concentration, is probably too weak to be resolved between the already existing bands a and b without specific isotopic substitution. Assignment of the remaining bands is settled through the calculation of force constants.

**Calculations.** As described above, we feel rather confident about the assignment of bands a, e, f, g, and h. The uncertainty arises for band b (a choice between the  $A_1$  mode for the  $C_{4v}$  or for the  $C_s$  isotopically substituted molecules) and bands c and d. We may decide the best assignment for these by comparing the calculated values with those observed (which of course are therefore not used as input). The best result is shown in Table II.

Table II. Comparison of Calculated with Observed Frequencies (cm<sup>-1</sup>) for  $\text{DRe}(\text{CO})_5$

$HRe(CO)_5^c$	16.34	16.96	0.282	0.328	0.583
$DRe(CO)_5$	16.37	16.98	0.281	0.330	0.582

<sup>a</sup> These force constants are relatively significant only to the first four ( $K_1, K_2$ ) or three figures ( $K_3, K_4, K_5$ ). For the possible accuracy of these constants see the discussion in the text of the accompanying publication.<sup>1b</sup> <sup>b</sup> For definition of force constants, see Figure 3 of ref 1b. <sup>c</sup> With  $\nu_{ReH}$  included. This calculation also yielded the following values:  $K_{ReH} = 1.984$ ,  $K_{H-CO(cis)} = 0.0006$ ,  $K_{H-CO(trans)} = 0.225$  mdyne/A.

reported for known carbonyl hydrides such as  $HMn(CO)_5$ , whose deuterium derivatives had also been studied.<sup>2a,3</sup> In our bands, upon repeating this work, we indeed found a shift in the carbonyl frequencies in the pair of compounds  $HRe(CO)_5$ – $DRe(CO)_5$  (see Experimental Section). No shifts within the limits of our experimental error were noticed for the analogous manganese derivatives, however. Calculations with the rhenium derivatives therefore were carried out in which the metal-hydrogen stretching frequency was included in the energy-factored ( $FG^{-1}$ ) matrix. In this case, all of the available carbonyl absorptions were placed in their assigned positions (determined by previous successful calculations carried out on the carbonyl modes alone). The results of this calculation are also shown in Table III (fourth row of numbers).

Several points should be noted. The mixing of  $\nu_{ReH}$  with the carbonyl stretching modes provides a satisfactory explanation for the observed shift to lower energy of the axial carbonyl band upon deuteration. This is illustrated in Figure 3. In  $HRe(CO)_5$ , the  $A_1$  purely carbonyl symmetry coordinate (mainly axial) and the  $A_1$  purely  $ReH$  symmetry coordinate (vertical dotted lines, top row of figure) will mix and produce observed bands at higher and lower energies (vertical solid lines, second row of Figure 3).

In  $DRe(CO)_5$ , however, the  $A_1$  purely carbonyl symmetry coordinate is separated by a large amount from  $A_1$   $ReD$  symmetry coordinate. Their mixing will be much decreased, and the observed bands (solid vertical lines, last row of figure) will suffer smaller energy shifts from the positions of the unmixed coordinates. Therefore, the carbonyl band assigned as  $A_1$  (axial) is observed to shift to lower energy (diagonal arrow) when  $\nu_{ReH}$  is replaced by  $\nu_{ReD}$  in going from  $HRe(CO)_5$  to  $DRe(CO)_5$ . The absence of similar effects in the spectra of the pentacarbonyl hydride and deuteride of manganese results no doubt from a smaller interaction in these derivatives between the  $\nu_{CO}$  and  $\nu_{MnH}$ . The shift, if any, on going to  $DMn(CO)_5$  must be below the limits of error of observation of these bands.

The observed shift on deuteration only for the  $A_1$  axial modes is reflected in the calculated interaction force constants between  $\nu_{ReH}$  and  $\nu_{CO}$ . The coupling of  $\nu_{ReH}$  with *trans*  $\nu_{CO}$  (about 0.22 mdyne/A) is about 400 times greater than the interaction between  $\nu_{ReH}$  and *cis*  $\nu_{CO}$  (0.0006 mdyne/A). This provides a quantitative measure of the *trans*-coupling effects of metal hydrides and carbonyl stretching modes observed in this work and also recently reported by Vaska for a number of other derivatives.<sup>9</sup>

The small changes in calculated force constants brought about by inclusion of  $\nu_{ReH}$  in the calculations (fourth row, Table III) gives us some added confidence in the procedure of energy factoring. If the changes resulting from such a relatively close-lying vibration (at 1822  $cm^{-1}$ ) are small, it is expected that those which would result from the other nearest vibrations (metal-carbon stretching and metal-carbonyl bending) around 600  $cm^{-1}$  would be even smaller still (assuming the coupling constants are of about the same order of magnitude) and can justifiably be left out when lack of data requires this. This makes it possible to carry out a vibrational analysis on an isolated portion of the spectrum such as the carbonyl stretching region.

**Exchange Reaction.** Confirmation of the  $^{13}C$  assignments was accomplished by exchange with  $^{13}C$ -enriched CO.

Both  $HMn(CO)_5$  and  $HRe(CO)_5$  exchange with  $^{13}CO$ ; the manganese compound exchanges at a much faster rate. The lower spectrum of Figure 1 shows  $HRe(CO)_5$  after 24 hr exchange with 50%  $^{13}C$ -enriched CO. Comparison with the normal spectrum of  $HRe(CO)_5$  (upper spectrum) shows very definite changes. Peak b has grown almost equal in intensity to a, one of the fundamentals of the all- $^{13}C$  molecule. The intensity of a has decreased as well since the total concentration of the all  $^{13}C$ -molecule has been reduced. Comparison of spectra shows that g is much more intense in the labeled hydride and that peaks d and h have both increased. These changes confirm our

assignment of these bands as  $^{13}\text{C}$ -carbonyl modes and, since *all* the  $^{13}\text{CO}$  peaks increase, indicate that both radial and axial carbonyls exchange. At no time in the exchange reaction does there appear to be a preference for radial or axial positions other than the increased probability of radial exchange since there are four radial to one axial carbonyls (assuming equal exchange rates for both groups). This is in agreement with Basolo, Braült, and Poë<sup>15</sup> who have found for

(15) F. Basolo, A. T. Braült, and A. J. Poë, *J. Chem. Soc.*, 676 (1964).

$\text{HMn}(\text{CO})_5$  from radiocarbon studies that all five CO's exchange at the same rate. The carbonyl spectrum after extensive exchange shows peaks characteristic of multiple  $^{13}\text{CO}$ -substituted molecules.

**Acknowledgment.** We wish to thank Dr. J. M. Smith, Mr. D. Hendrickson, R. Bau, and R. Bagula for valuable discussions and for assistance at several times with the computer calculations. We also acknowledge the UCLA Computation Facility for making available intramurally supported computer time, and Miss Karen Mehner for preparation of the figures.

## A Nuclear Magnetic Resonance Study of $\sigma$ -Cyclopentadienyl(triethylphosphine)copper(I)<sup>1</sup>

George M. Whitesides and John S. Fleming

*Contribution from the Department of Chemistry, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139. Received December 14, 1966*

**Abstract:** The nmr spectrum of cyclopentadienyl(triethylphosphine)copper(I) has been examined as a function of temperature between 0 and  $-70^\circ$ . The high-temperature spectrum of the cyclopentadienyl group consists of a single line; the corresponding low-temperature spectrum is composed of three lines having relative areas 2:2:1. The latter spectrum requires that the organometallic compound exist in solution as a copper  $\sigma$ -cyclopentadienide. Analysis of the spectral line shapes in the exchange-broadened region indicates that the averaging of chemical shifts observed at high temperatures must occur by either a sequence of 1,2 or 1,3 shifts of the metal atom around the cyclopentadienyl ring, and that it cannot take place by a sequence of random shifts. Chemical shift data are tentatively interpreted to support the 1,3-shift mechanism for the averaging.

Compounds containing a  $\sigma$  bond connecting carbon and copper(I) usually show a low order of thermal stability.<sup>2</sup> Details of the factors responsible for the thermal lability of this class of organometallic compounds are not well understood: the stability of the incipient radical formed during homolytic cleavage of the carbon-metal bond,<sup>3</sup> the ionic character of the bond,<sup>4</sup> and the magnitude of the energy separating the highest filled and lowest unfilled  $\sigma$  molecular orbitals<sup>5</sup> have been variously proposed to determine the stability of these and other transition metal alkyls.

As part of an investigation of the structural features influencing the rate of decomposition of several organocopper(I) reagents, we have had opportunity to examine some of the properties of cyclopentadienyl(triethylphosphine)copper(I).<sup>6</sup> Wilkinson and Piper have formulated this compound as a  $\sigma$ -cyclopentadienide, rather than a  $\pi$ -cyclopentadienide, on the basis of

spectral evidence.<sup>6</sup> However, the thermal stability of this material is unexpectedly greater than that of other simple alkylcopper(I) compounds; moreover, its room-temperature nmr spectrum shows only a single sharp peak for the protons on the cyclopentadienyl ring.<sup>6b</sup> The possibility that cyclopentadienyl(triethylphosphine)copper is a member of the group of metal  $\sigma$ -cyclopentadienides characterized by rapid migration of the metal atom between carbon atoms in the cyclopentadienyl ring<sup>6b-8</sup> has led us to examine the temperature dependence of its nmr spectrum, in hope of learning more about its structure and the reasons for its unexpected thermal stability. In this paper we wish to report evidence which confirms the structure suggested by Piper and Wilkinson, and which sheds some light on the process which averages the chemical shifts of the cyclopentadienyl protons.

### Results

The nmr spectrum of the cyclopentadienyl protons of cyclopentadienyl(triethylphosphine)copper in sulfur dioxide solution at  $0^\circ$  consists of a sharp line at 6.30 ppm downfield from internal tetramethylsilane (Figure 1); resonances due to triethylphosphine occur at higher field and are omitted from this figure. As the temperature of the sample is lowered, the cyclopentadienyl proton resonance broadens and splits into three lines

Figure 1. Nmr spectra of the cyclopentadienyl protons of  $\eta$ -cyclopentadienyl(triethylphosphine)copper(I) in sulfur dioxide solution as a function of temperature. The three peaks in the low-temperature spectrum occur at 6.95, 6.57, and 4.46 ppm from internal tetramethylsilane.

#### 1,2 shifts

$$I(\omega) \propto$$

$$\text{Re} \left[ (2,2,1) \begin{pmatrix} -i(\omega_1 - \omega) - 1/T_2^1 - 1/\tau & 0.5/\tau \\ 0.5/\tau & -i(\omega_2 - \omega) - 1/T_2^2 - 0.5/\tau \\ 1/\tau & 0 & -i(\omega_3 - \omega) - 1/T_2^3 - 1/\tau \end{pmatrix}^{-1} \begin{pmatrix} 1 \\ 1 \\ 1 \end{pmatrix} \right] \quad (1)$$

at 6.95, 6.57, and 4.46 ppm, having relative areas approximately 2:2:1. Solutions of cyclopentadienyl(triethylphosphine)copper, in the concentration range used in these studies, crystallize at temperatures below approximately  $-40^\circ$  if allowed to stand. In consequence, spectra taken in the exchange-broadened region of the spectrum were obtained on supersaturated solutions. Attempts to lower the temperature of the sample below  $-70^\circ$  to examine spin coupling in the true slow-exchange limit were thwarted by crystallization of the organometallic compound from solution.

The observation of three distinct signals for the cyclopentadienyl protons in the low-temperature spectrum of cyclopentadienyl(triethylphosphine)copper immediately establishes that this compound should be formulated as a copper(I) alkyl (1) containing a carbon-copper  $\sigma$  bond, rather than as a copper(I)-olefin  $\pi$  complex.

The highest field peak in the observed spectrum, having relative area 1, can be safely assigned to the  $\text{CHCu}$  proton; the two lower field peaks are due to the two nonequivalent types of vinylic protons. Unfortunately,

it is not presently possible to assign chemical shifts to these protons unambiguously. In the discussions which follow, we make the assumption that the resonance occurring at lowest field can be assigned to the protons in site 1 of 1. Some justification for this assumption will be offered below.

The single line observed in the high-temperature spectrum of this compound is most easily rationalized on the basis of rapid hopping of the copper atom between carbon atoms in the cyclopentadienyl ring. In principle, this hopping of the metal atom might take place by any one of three distinct paths: each exchange might shift the copper atom only between adjacent carbon atoms (for example,  $1 \rightarrow 2a$ ); the exchange might shift the copper atom specifically in a 1,3 manner ( $1 \rightarrow 2b$ ); or exchange might occur indiscriminantly by a random mixture of 1,2 and 1,3 shifts.

The unsymmetrical collapse of the resonance due to the vinyl protons observed in the exchange-broadened region offers a method of distinguishing between these alternatives. By following the method developed by Kubo<sup>9a</sup> and by Sack,<sup>9b</sup> theoretical line shapes can be calculated for each of these possible exchange schemes. In particular, for a sequence of 1,2 hops, the full line-shape function  $I(\omega)$ , giving the relative intensity of absorption in the spectrum at frequency  $\omega$ , is given by eq 1. This equation applies to the labeling of the cyclopentadienyl protons indicated in 1. Here, for example,  $\omega_1$  is the chemical shift of the protons at site 1,  $T_2^1$  is the relaxation time for the protons at this site in the

absence of exchange, and  $\tau$  is the mean time the copper atom spends at each carbon atom between exchanges. Re indicates that only the real part of the expression inside the brackets is considered. The appropriate kinetic transfer matrices  $K$  for a 1,3-hopping scheme and for random exchange are given by eq 2 and 3. The corresponding line-shape functions are obtained by substituting these matrices for the exchange terms in eq 1.

#### 1,3 shifts

$$K = \begin{pmatrix} -0.5/\tau & 0.5/\tau & 0 \\ 0.5/\tau & -1/\tau & 0.5/\tau \\ 0 & 1/\tau & -1/\tau \end{pmatrix} \quad (2)$$

#### Random shifts

$$K = \begin{pmatrix} -0.75/\tau & 0.5/\tau & 0.25/\tau \\ 0.5/\tau & -0.75/\tau & 0.25/\tau \\ 0.5/\tau & 0.5/\tau & -1/\tau \end{pmatrix} \quad (3)$$

Line shapes calculated using eq 1-3 for several values of the pre-exchange lifetime  $\tau$  are given in Figures 2-4. In these calculations, no attempt was made to take into consideration spin-spin coupling in the slow-exchange

Figure 2. Calculated line shapes for the cyclopentadienyl protons as a function of the mean preexchange lifetime  $\tau$  (in sec) between successive 1,2 hops. These spectra are based on the assumption the resonance at lowest field can be assigned to the protons in of 1.

ra. Indeed,  $T_2$  (here set equal to 0.034 sec for all sites) was adjusted to give line widths at slow angle which approximated those of the vinylic protons in the observed spectra. Since this value includes contributions to the line shape from both motion and from spin-spin coupling, the calculated width in the fast exchange limit is appreciably larger than the observed line width. Nonetheless, qualitative features of these calculated spectra are reliable, and, in particular, the unsymmetrical exchange broadening calculated for the vinyl proton resonances in the 1,2- and 1,3-hopping schemes is significant.

The asymmetry in the calculated spectra is physically reasonable if it is remembered that in these schemes exchange changes the precession frequencies of two kinds of vinyl protons by different amounts. For example, for successive 1,2 shifts, the precession frequency of each of the protons labeled  $H_1$  in 1 changes with equal probability by either  $\sim 100$  Hz (if exchange transfers the proton considered to the  $CHCu$  site) or  $\sim 10$  Hz (if it is transferred to the second vinylic site). Similarly, the corresponding changes in the precession frequency of each of the protons labeled  $H_2$  are either  $\sim 10$  Hz or 0 Hz. Since the relative line broadening for the two types of protons is related to the relative "uncertainty" in their precessional frequencies, the resonance of the proton experiencing the larger changes in frequency per unit time would be expected to broaden more rapidly on increasing the rate of exchange.<sup>10</sup> Comparison of the calculated and observed spectra in the region of exchange broadening indicates that the

For a more detailed presentation of this argument, see S. Meizer, *Z. Elektrochem.*, **64**, 50 (1960); see also ref 8.

Figure 3. Calculated line shapes for the cyclopentadienyl protons as a function of  $\tau$  for successive 1,3 hops.

Figure 4. Calculated line shapes for the cyclopentadienyl protons as a function of  $\tau$  for random hops.

averaging of the chemical shifts of the cyclopentadienyl protons occurs by a sequence of 1,3 hops of the metal atom around the ring, *provided* that the assignment of relative chemical shifts to the two kinds of vinylic protons is correct.<sup>11</sup> If this assignment is

(11) Similar calculations have been applied to a number of related problems: see, for examples, C. MacLean and E. L. Mackor, *Discuss. Faraday Soc.*, **28**, 196 (1960).

reversed, the spectra calculated for the random exchange scheme are unaffected, but the spectra calculated for 1,2- and 1,3-hopping schemes must be interchanged. In this circumstance, comparison of calculated and observed spectra would indicate that averaging occurred by a 1,2-hopping process.

The temperature dependences observed for the spectrum of this organometallic compound in propionitrile and petroleum ether solutions were qualitatively similar to that observed in sulfur dioxide, although the chemical shift of the  $CHCu$  proton was appreciably solvent dependent. Further, the copper compound could be recovered from sulfur dioxide solution without apparent change. These observations exclude the possibility that the compound whose spectrum was observed in sulfur dioxide was actually an adduct of the organo-copper compound with sulfur dioxide.<sup>12</sup> Spectra taken in triethylamine or triethylphosphine solutions showed only a single line for the cyclopentadienyl protons at temperatures as low as  $-70^\circ$ . Spectra taken in solutions consisting of mixtures of sulfur dioxide and triethylamine or triethylphosphine showed qualitatively the same changes in line shapes as were observed in pure sulfur dioxide; in particular, the same asymmetry was observed in the vinyl proton signals in the exchange-broadened region. However, lower temperatures were required to produce exchange broadening in the mixed solvents than in sulfur dioxide alone.

No direct evidence is available on the extent of association of cyclopentadienyl(triethylphosphine)copper in solution. However, the observations that this compound sublimates readily, and that its mass spectrum shows a clearly defined parent ion ( $m/e$  247 and 249) but no evidence of dimeric or more highly aggregated species, suggest that it is probably unassociated in the vapor phase, and that by inference it is probably also unassociated in a hydrocarbon solvent.<sup>13</sup> It is of some further interest that the only other relatively abundant ions in the spectrum which clearly contain copper correspond to  $(C_5H_5)_2PCu^+$  ( $m/e$  181 and 183). The absence of a strong peak corresponding to  $C_5H_5Cu^+$  lends further support to a formulation of this compound as a  $\sigma$ -cyclopentadienide.<sup>14</sup>

## Discussion

Comparison of the observed and calculated temperature dependence for the spectra of  $\sigma$ -cyclopentadienyl(triethylphosphine)copper(I) permits the conclusion that the averaging of chemical shifts observed at high

(12) Insertion of sulfur dioxide into carbon-metal bonds is well known in the chemistry of other transition metal alkyls: J. P. Bibler and A. Wojcicki, *J. Am. Chem. Soc.*, **88**, 4862 (1966), and references therein.

(13) Other copper(I) and silver(I) organometallic compounds are probably associated both in solution in the crystalline state: P. W. R. Corfield and H. M. M. Shearer, *Acta Cryst.*, **16**, A71 (1963); **20**, 502 (1966); A. F. Wells, *Z. Krist.*, **94**, 447 (1936); F. G. Mann, D. Purdie, and A. F. Wells, *J. Chem. Soc.*, 1503 (1936); D. Blake, G. Calvin, and G. E. Coates, *Proc. Chem. Soc.*, 396 (1959); G. E. Coates and C. Parkin, *J. Inorg. Nucl. Chem.*, **22**, 59 (1961).

(14)  $\pi$ -Cyclopentadienylmetal compounds ordinarily show prominent peaks corresponding to  $C_5H_5M^+$ .<sup>15</sup> Although the presence of an ion,  $C_5H_5Cu^+$  ( $m/e$  128 and 130), cannot be excluded in the spectrum, it certainly does not provide a major pathway for fragmentation.

(15) For example, see R. G. Denning and R. A. D. Wentworth, *J. Am. Chem. Soc.*, **88**, 4619 (1966).

temperatures is not the result of *random* hopping of the metal atom between carbon atoms; however, the question of whether the averaging reflects a sequence of successive 1,2 or 1,3 shifts can be answered unambiguously only by correctly assigning chemical shifts to the two kinds of olefinic protons. This assignment cannot at present be made with great assurance.

The relative magnitudes of the coupling constants between the  $CHCu$  proton and the two vinyl protons cannot easily be used in assigning chemical shifts, both because the poor resolution in the spectra at the lowest temperatures utilized makes detailed spectral analysis impractical, and because analogous coupling constants in the few model compounds which have been examined suggest that these two coupling constants have approximately the same magnitude.<sup>16</sup> An assignment based on chemical-shift correlations suffers from the scarcity of data from model compounds. Nonetheless, the spectra of cyclopentadienyltrimethylsilane<sup>7</sup> and -trimethylgermane,<sup>7</sup>  $\pi$ -cyclopentadienyliron dicarbonyl  $\sigma$ -cyclopentadienide,<sup>8</sup> and cyclopentadienyl(triethylphosphine)copper share in common the feature that the resonance of at least one of the two kinds of vinylic protons of the cyclopentadienyl group of each compound occurs near 6.6 ppm. If it is assumed that the chemical shift of the vinylic protons which are four bonds removed from the metal atom will be relatively insensitive to the nature of the metal and its ligands,<sup>19</sup> the 6.57-ppm resonance in the copper organometallic compound can be tentatively assigned to  $H_2$  of **1**, and consequently, the 6.95-ppm resonance can be assigned to  $H_1$ . Provided these assignments are correct, the high-temperature averaging of the chemical shifts must take place *via* 1,3 shifts of the copper atom.<sup>20</sup> However, this conclusion must obviously remain tentative until further experimental work on related compounds is available.

Details of the mechanism of the metal atom shift might be examined by determining the influence of appropriate solution variables on the rate of this reaction. Unfortunately, the spin-spin splitting present in the slow exchange limit severely limits the accuracy

(16) Manatt and Elleman have observed  $J_{12} = +2.02$  Hz and  $J_{13} = -1.98$  Hz for indene,<sup>17</sup> and  $J_{12} = +1.3$  Hz and  $J_{13} = -1.5$  Hz for cyclopentadiene.<sup>18</sup> However, both three- and four-bond couplings are

strongly dependent on the geometry of the molecular fragment concerned. In consequence, coupling constants in these hydrocarbons may not provide reliable model parameters for the corresponding coupling constants in the organometallic compounds. For reviews of theoretical and experimental evidence pertinent to the geometrical dependence of these couplings, see M. Barfield, *J. Chem. Phys.*, **41**, 3825 (1964); A. A. Bothner-By, *Advan. Magnetic Resonance*, **1**, 195 (1965); E. W. Garbisch, Jr., *J. Am. Chem. Soc.*, **86**, 5561 (1964).

(18) S. L. Manatt, personal communication.

(19) The chemical shifts observed for the methyl and methylene protons of ethyl-substituted organometallic compounds offers some support for this assumption: A. Davison, J. A. McCleverty, and G. Wilkinson, *J. Chem. Soc.*, 1133 (1963); M. L. Maddox, S. L. Stafford, and H. D. Kaesz, *Advan. Organometal. Chem.*, **3**, 1 (1965).

(20) This type of equilibration is known in allylic organometallic compounds: G. M. Whitesides, J. E. Nordlander, and J. D. Roberts, *Discussions Faraday Soc.*, **34**, 185 (1962); K. C. Ramey and G. L. Statton, *J. Am. Chem. Soc.*, **88**, 4387 (1966), and references therein.

tailed kinetic analysis.<sup>21</sup> Qualitatively, the significant rate increase observed on adding  $\sigma$ -donor ligand to the sample suggests that, in going to the transition state for the metal atom shift, the compounds dissociate to an appreciable extent along the path of dissociated cyclopentadienide anion and metal ion, and that the added ligand serves to increase the rate by stabilizing the increased partial positive charge on the metal atom during the shift. However, the tendency of the unsymmetrical mode of collapse of the signals in the presence of added donor ligands indicates that even under these circumstances dissociation does not become complete.

It is of some interest that the temperature dependence of the nmr spectrum of  $\pi$ -cyclopentadienyliron dicarbonyl  $\sigma$ -cyclopentadienide has been interpreted as indicating that the metal atom in this compound shifts out of the cyclopentadienyl ring by a sequence of 1,2 shifts.<sup>15</sup> If both this interpretation and that proposed for the organocopper reagent are correct, the difference between these compounds poses an interesting problem. However, the assignment of the vinylic proton chemical shift in the iron organometallic compound was based on the assumption that the magnitude of the three-bond coupling between the  $CHFe$  proton and the vicinal proton was greater than that of the corresponding  $CHH$  coupling, and the ambiguity in this type of assignment has already been indicated.<sup>16</sup> In consequence, comparison of the two compounds is most appropriately deferred until the stereochemistry of the metal shift in each has been more clearly defined.

## Experimental Section<sup>22</sup>

$\sigma$ -Cyclopentadienyl(triethylphosphine)copper was prepared using a modification of Wilkinson and Piper's method.<sup>6</sup> Commercial cuprous oxide (3.6 g), 10 ml of freshly distilled cyclopentadiene, 7 ml of triethylphosphine, and 20 ml of petroleum ether (bp 30–60°) were refluxed under a nitrogen atmosphere with magnetic stirring for 2 hr and then allowed to stir at ambient temperature for 6 hr. The solvent was removed under reduced pressure, and the resulting brown-black syrup was transferred in a nitrogen-filled glove bag directly to a sublimation apparatus. The product was obtained as hard white or pale yellow-green crystals by slow sublimation at 60° and 0.1 mm. The crystals were moderately stable in the absence of oxygen; solutions of the organometallic were much less stable.

Nmr samples were prepared by transferring a suitable quantity of the freshly sublimed material to a flame-dried nmr tube under nitrogen. The tube was capped with a serum stopper and cooled to the temperature of a Dry Ice–acetone bath, at which temperature, sulfur dioxide was condensed into the tube. The sample was warmed briefly to approximately –35°, to allow the organocopper reagent to dissolve, and then inserted into the precooled (–40°) probe of the nmr spectrometer. If the sample was permitted to warm to temperatures above –40° for more than approximately 5 min, decomposition of the sample introduced significant absorption due to impurities in the olefin absorption region.

**Acknowledgments.** We wish to express our thanks to Dr. Robert Siekman for his help in obtaining mass spectra, and to Drs. S. L. Manatt and D. D. Elleman for permission to use their data prior to publication.

(22) Nmr spectra were taken at 60 MHz using a Varian A-60 spectrometer equipped with a V-6040 variable-temperature probe and controller. Sweep widths were calibrated using a Krohn-Hite Model 450 oscillator and a Hewlett-Packard Model 524 electronic counter. Calibration of the temperature controller was accomplished by measuring peak separations in a methanol sample. Mass spectra were determined with a Hitachi Perkin-Elmer RMU-6D spectrometer. Spectral calculations were carried out using an IBM 7094 computer, and spectra were plotted by a Calcomp plotter.

## Mixed Ligand Chelates of Uranium(IV)<sup>1,2</sup>

G. H. Carey and A. E. Martell<sup>3</sup>

*Contribution from the Department of Chemistry, Illinois Institute of Technology, Chicago, Illinois. Received December 14, 1966*

**Abstract:** Potentiometric studies are described for mixed ligand U(IV) chelate formation with ethylenediamine-tetraacetic acid (EDTA) and nitrilotriacetic acid (NTA) as primary ligands. Secondary ligands studied are salicylic acid (SA), 5-sulfosalicylic acid (SSA), disodium 1,2-dihydroxybenzene-3,5-disulfonate (Tiron), pyrocatechol (PY), 5-sulfo-8-hydroxyquinoline (HQS), disodium 1,8-dihydroxynaphthalene-3,6-disulfonate (CS), *o*-phthalate (Ph), and iminodiacetic acid (IMDA). For the mixed ligand chelate systems containing EDTA, combination with the primary ligand is complete before combination with the secondary ligand takes place. For the less stable NTA systems, overlapping of reactions of the primary and secondary ligands is much more extensive. The relative magnitudes of the equilibrium constants for combination of secondary ligands with the U(IV)–EDTA chelate are  $CS > Tiron > PY > SSA > HQS > IMDA \gg Ph$ . The mixed ligand chelates of U(IV) are more stable than those of Th(IV) by 1–3 log  $K$  units.

Uranium(IV) and thorium(IV) ions are generally considered to have coordination numbers of about 12 in solution and probably form dodecahedral complexes.

This work was supported by the U. S. Atomic Energy Commission Contract No. AT(11-1) 1020.

Figure 1. Potentiometric titrations of mixed ligand chelate systems of U(IV) and EDTA; all solutions are  $2.0 \times 10^{-3} M$  in U(IV) and adjusted to  $\mu = 0.10$  with KCl at the start of the titration;  $m$  = moles of base added per mole of metal ion: (A) 1:1 U(IV)-EDTA; (B) 1:1:1 U(IV)-EDTA-PY; (C) 1:1:1 U(IV)-EDTA-Tiron; (D) 1:1:1 U(IV)-EDTA-IMDA; (E) composite curve for the 1:1:1 U(IV)-EDTA-Tiron system; - - - indicates drifting of  $-\log [H^+]$  readings; EDTA was introduced as the disodium salt.

bidentate ligand could therefore fill these two vacant sites to give a mixed ligand chelate. In the case of a 1:1 complex formed between U(IV) and a quadridentate ligand such as NTA (nitrilotriacetic acid), there are four coordination sites left upon for hydrolysis and olation reactions which, because of their complexity, would be almost impossible to characterize. However, on the addition of two bidentate groups to complete the coordination sphere of the U(IV), a stable mixed ligand complex, resistant to hydrolysis, might conceivably be formed.

In this study, various bidentate ligands are combined with aqueous EDTA and NTA chelates of U(IV), in order to completely fill the coordination sphere of the metal. Although no data have been previously reported on mixed ligand chelates of U(IV), studies of mixed ligand complexes involving thorium(IV),<sup>5</sup> zirconium(IV),<sup>6</sup> the rare earths,<sup>7</sup> and other metals<sup>8</sup> have been published. Comparison of mixed ligand chelate formation of U(IV) with that of Th(IV), and of other metal ions, would yield useful information about the nature of the aqueous complex chemistry of these metal ions.

### Experimental Section

**Materials. Uranium(IV) Solution.** The preparation, storage, and standardization of the unique U(IV)-U(III) stock solution are described in detail in a previous paper.<sup>9</sup> The final solution is approximately 0.026 M in  $UCl_4$  and 0.050 M in excess HCl.

**Ligands.** Fisher certified samples of the disodium salt of N,N,N',N'-ethylenediaminetetraacetic acid (EDTA) and potassium

acid phthalate (Ph) were used. The 5-sulfosalicylic acid (SSA), salicylic acid (SA), chromotropic salt (disodium 1,8-dihydroxynaphthalene-3,6-sulfonate (CS)), pyrocatechol (PY), and 8-hydroxy-5-quinolinesulfonic acid (HQS) were purchased from the Eastman Kodak Co., while the nitrilotriacetic acid (NTA) and iminodiacetic acid (IMDA) were obtained through the courtesy of the Dow Chemical Co. Tiron (disodium 1,2-dihydroxybenzene-3,5-disulfonate) was obtained from the La Motte Chemical Products Co.

All ligands used were of reagent grade of the highest available purity and were recrystallized whenever necessary. In the case of the water-soluble ligands, a stock solution 0.020 M in the ligand was prepared and standardized potentiometrically with a standard solution of NaOH. With relatively insoluble ligands as well as ligands whose aqueous solutions are susceptible to oxidation or to some other form of decomposition, the purity of the sample was determined and the ligand was introduced into the experimental solution as an accurately weighed solid.

**Apparatus and Procedure.** A Beckman Model G pH meter was used to determine hydrogen ion concentrations. Potentiometric measurements were carried out in a magnetically stirred, jacketed titration cell of 70-ml capacity fitted with nitrogen inlet and outlet tubes, microburet delivery tube, and glass and saturated calomel extension electrodes. Measurements were made at a temperature of 25.3°. The ionic strength was maintained at 0.10 M by the addition of potassium chloride to the experimental solution. Purified nitrogen was bubbled through the solution in order to exclude carbon dioxide. The electrode system was calibrated with acetic acid, HCl, and NaOH to give  $-\log [H^+]$  values directly.

A measured quantity of the uranium(IV) chloride stock solution was run from the inert atmosphere buret directly into the titration cell already containing a solution of potassium chloride and the appropriate amount of the acid form of the ligands. Oxygen was then run through the solution for 3 min to oxidize the U(III) present back to U(IV), and the nitrogen was bubbled through the solution to purge the system of oxygen. Nitrogen was kept flowing continuously throughout the rest of the potentiometric determination to preclude the possibility of any oxygen coming into contact with the uranium(IV) solution. The potentiometric titration was then carried out in the usual manner.

**Calculations.** Stability constants of mixed ligand chelates were calculated in favorable cases for the combination of the 1:1 EDTA chelates with a second ligand with methods similar to those employed by Thompson and Loraas.<sup>7</sup>

### Results

U(IV)-EDTA-Tiron, U(IV)-EDTA-CS, U(IV)-EDTA-PY. The 1:1:1 U(IV)-EDTA-Tiron solution yields a potentiometric curve (Figure 1, curve C) exhibiting a long low buffer region with an extremely sharp inflection at  $m = 4.00$ . The 1:1 U(IV)-EDTA chelate is completely formed at the start of the titration since the initial hydrogen ion concentration shows that there are two free hydrogen ions present in solution per U(IV) ion. The part of the buffer region from  $m = 0$  to  $m \approx 2.0$  consists of the titration of the two free hydrogen ions from the 1:1 U(IV)-EDTA chelates. This can be verified by the perfect match of the 1:1 U(IV)-EDTA curve (Figure 1, curve A) with the mixed ligand curve up to an  $m$  value of about 1.5.

From  $m \approx 1.5$  to  $m = 4.00$  the two hydroxyl groups on the Tiron become bound to the 1:1 chelate to form the 1:1:1 mixed ligand chelate. The buffer region terminates with an extremely sharp inflection at  $m = 4.00$  indicating that at this point the mixed ligand chelate is completely formed.

Thus the mixed ligand chelate is formed in two steps. In the first step from  $m = 0$  to 2.00 the completely formed 1:1 EDTA-U(IV) species is the only chelate present, while from  $m = 2.00$  to 4.00 the Tiron becomes bound to the 1:1 U(IV)-EDTA complex to form the 1:1:1 mixed ligand chelate. This conclusion is strengthened by visual evidence, whereby the solution

green in color because of the presence of the U(IV)-EDTA chelate up to about  $m = 2.50$  gradually yellow between  $m = 2.50$  and 4.00, and completely yellow at  $m = 4.00$ . This yellow probably due to the addition of the Tiron to the U(IV)-EDTA chelate to form the mixed ligand

as further proof for the existence of the mixed ligand is the comparison of the 1:1:1 U(IV)-EDTA-Tiron curve with the composite curve, E. Curve C of Figure 2 shows a difference in slope and a large lowering of the buffer region between  $m = 2.00$  and 4.00, relative to the composite, which was calculated on the assumption that no mixed ligand chelate is formed. This difference of increased interaction in the presence of two ligands indicates the formation of a relatively stable mixed ligand chelate.

The 1:1:1 U(IV)-EDTA-CS (where CS = disodium 2-hydroxynaphthalene-3,6-sulfonate) curve also extends along low buffer region with an extremely sharp inflection at  $m = 4.00$ . It is superimposable on the 1:1:1 U(IV)-EDTA-Tiron curve up to  $m = 4.00$ , lying slightly from the latter on further addition of Tiron.

Here also a color change is noted between  $m = 2.50$  and 4.00 and a comparison of the 1:1:1 U(IV)-EDTA-CS experimental curve with the composite curve from the same system yields a difference in the buffer region between  $m = 2.00$  and 4.00. Therefore, it is evident that this system must undergo the same reactions as that of the Tiron system, with the 1:1 U(IV)-EDTA being present from  $m = 0.00$  to 2.00, with the formation of the mixed ligand chelate between  $m = 2.00$  and 4.00.

The 1:1:1 U(IV)-EDTA-PY system (where PY = pyrocatechol) furnishes a potentiometric curve (Figure 1, curve A) that has a very poor sloping inflection at  $m = 2.00$  and a well-defined inflection exactly at  $m = 4.00$ . A titration  $[H^+]$  concentration shows that the 1:1 U(IV)-EDTA complex is completely formed at the start of the titration, and the lower buffer region up to  $m = 2.00$  merely represents the titration of the 2 equivalent hydrogen ion from the 1:1 U(IV)-EDTA chelate. The second buffer region between  $m = 2.00$  and 4.00 corresponds to the hydroxyl groups on the pyrocatechol become involved in the 1:1 chelate to form the 1:1:1 U(IV)-EDTA-PY mixed ligand chelate. The green color up to about  $m = 2.7$  changes completely to yellow by  $m = 4.00$ . Comparison of the 1:1:1 U(IV)-EDTA-PY experimental curve with the composite curve calculated for no mixed ligand chelate formation shows a difference in shape and lower buffer region between  $m = 2.00$  and 4.00. These observations indicate the formation of the mixed ligand chelate in the second buffer region. It is also evident that the formation of the 1:1:1 U(IV)-EDTA-PY mixed ligand chelate occurs at a much higher pH than that of the 1:1 U(IV)-EDTA-Tiron mixed ligand complex.

It is of interest to compare the above three mixed ligand systems with the behavior of the simple 1:1 U(IV)-EDTA (Figure 2, curve A) chelate compound. In the latter, hydrolysis occurs in the 4.0–5.5 pH range to give a binuclear chelate. With the 1:1:1 U(IV)-EDTA-Tiron system there is no drifting of  $[H^+]$  values, or precipitation, which would denote

Figure 2. Potentiometric titrations of mixed ligand chelate systems of U(IV) and EDTA; all solutions were adjusted to  $\mu = 0.10$  with KCl at the start of the titration;  $m$  = moles of base added per mole of metal ion: (A) 1:1:1 U(IV)-EDTA-Ph,  $2.0 \times 10^{-3} M$ ; (B) 1:1:1 U(IV)-EDTA-SA,  $2.0 \times 10^{-3} M$ ; (C) 1:1:1 U(IV)-EDTA-HQS,  $7.5 \times 10^{-4} M$ ; (D) 1:1:1 U(IV)-EDTA-HQS,  $2.0 \times 10^{-3} M$ ; (E) 1:1:1 U(IV)-EDTA-SSA,  $2.0 \times 10^{-3} M$ ; ---- indicates drifting of  $-\log [H^+]$  readings; EDTA was introduced as the disodium salt.

a tendency toward hydrolysis and possibly polymerization, while with CS and PY drifting is noted starting around  $-\log [H^+] = 9.4$  and 10.6, respectively. Thus it is seen that there is a remarkable difference between the hydrolysis tendencies of the chelate and the mixed ligand chelate and that the addition of a second binuclear ligand effectively hinders hydrolysis and polymerization.

U(IV)-EDTA-SA, U(IV)-EDTA-SSA, U(IV)-EDTA-IMDA, U(IV)-EDTA-Ph. The addition of an equivalent of SA (salicylic acid), SSA (5-sulfosalicylic acid), or IMDA (iminodiacetic acid) to the U(IV)-EDTA chelate produced three mixed ligand systems, each of which yielded analogous potentiometric curves indicating reaction of a similar nature. In the 1:1:1 U(IV)-EDTA-SA system (Figure 2, curve B) and the 1:1:1 U(IV)-EDTA-IMDA system (Figure 1, curve D), the titration curves exhibit a single long buffer region at low  $-\log [H^+]$  values which terminates in a fairly sharp inflection at  $m = 4.00$ , while the 1:1:1 U(IV)-EDTA-SSA curve (Figure 2, curve E) yielded a similar curve with an inflection at  $m = 5.00$ . The lower part of the buffer region from  $m = 0.00$  to 3.00 for the 1:1:1 U(IV)-EDTA-SA and 1:1:1 U(IV)-EDTA-IMDA curves, and from  $m = 0.00$  to 4.00 for the 1:1:1 U(IV)-EDTA-SSA curve, corresponds to the titration of the hydrogen ion displaced from the 1:1 U(IV)-EDTA complex, and the acidic hydrogen ions from the secondary ligand (1 equiv in the case of the SA and IMDA and 2 in the case of the SSA). Subsequently, between  $m = 3$  and 4 with SA and IMDA and  $m = 4$  and 5 for SSA, an additional hydrogen ion is displaced from the ligand, showing the formation of the 1:1:1 mixed ligand chelates U(IV)-EDTA-SA, U(IV)-EDTA-IMDA, and U(IV)-EDTA-SSA, respectively.

Figure 3. Potentiometric titration of mixed ligand chelate systems of U(IV) and NTA. All solutions were adjusted to  $\mu = 0.10$  with KCl at the start of the titration;  $m$  = moles of base added per mole of metal ion: (A) 1:4 U(IV)-Tiron,  $1.0 \times 10^{-3} M$  in U(IV), also 1:1.5 U(IV)-Tiron,  $1.0 \times 10^{-3} M$  in U(IV); (B) 1:2 U(IV)-NTA,  $1.0 \times 10^{-3} M$  in U(IV); (C) 1:1:2 U(IV)-NTA-Tiron,  $2.0 \times 10^{-3} M$  in U(IV); (D) composite curve derived from A and B; (E) 1:1:2 U(IV)-NTA-HQS,  $2.0 \times 10^{-3} M$  in U(IV); - - - indicates drifting of  $-\log [H^+]$  readings; . . . indicates the presence of precipitate in the solution; for curves A and B the actual  $m$  values are twice the  $m$  values shown.

Hydrolysis is noted above  $-\log [H^+] = 8.5$  for SA and SSA, while with IMDA no drifting is noticed even at a  $-\log [H^+]$  value of 9.0.

The 1:1:1 U(IV)-EDTA-Ph curve (Figure 2, curve A) (where Ph = potassium acid phthalate) exhibits a buffer region which culminates in a sloping and almost imperceptible inflection around  $m = 3.00$ . Since the composite curve for this system assuming no mixed ligand chelate formation predicts a slightly higher  $-\log [H^+]$  value than the experimental curve between  $m = 2.00$  and  $3.00$ , it is concluded that a mixed ligand chelate is being formed in this region. This mixed ligand chelate once formed undergoes hydrolysis around  $-\log [H^+] = 6.50$ , above which drifting of the  $-\log [H^+]$  value is noted.

**U(IV)-EDTA-HQS.** The 1:1:1 U(IV)-EDTA-HQS system (HQS = 8-hydroxy-5-quinolinesulfonic acid),  $2.0 \times 10^{-3} M$  in U(IV), yields a potentiometric curve (Figure 2, curve D) which has a long buffer region at low  $-\log [H^+]$  culminating in a well-defined inflection at  $m = 4.00$ . Beyond this inflection there is another buffer region which is concentration independent (Figure 2, curves C and D) and which culminates in a sloping inflection around  $m = 5.00$ . Thus in the lower buffer region a 1:1:1 mixed ligand chelate is formed, while in the second buffer region a distinct monohydroxo mixed ligand chelate is formed, with a calculated  $pK_1 = 7.14 \pm 0.01$  for the two different concentrations. Thus the mixed ligand chelate formed in the lower buffer region is not very stable and undergoes hydrolysis to mononuclear monohydroxo mixed ligand chelate around  $-\log [H^+] = 7.1$ . However, this monohydroxo mixed chelate, once formed, is quite stable since drifting of the pH meter readings indicating further

hydrolysis was noted only at very high  $-\log [H^+]$  values above 10.0.

**U(IV)-NTA, U(IV)-NTA-HQS.** The 1:1 U(IV)-NTA system (not shown) is characterized by a colloidal precipitate and drifting of pH values from the start of the titration. There is a single inflection at  $m = 4.75$ . Consequently the 1:1 U(IV)-NTA chelate undergoes hydrolysis and ololation reactions, forming an insoluble hydroxo chelate, even at very low  $-\log [H^+]$  values.

The potentiometric titration curve of the 1:1:2 U(IV)-NTA-HQS system (Figure 3, curve E) has a long, low pH buffer region from  $m = 0$  to 7.0, which terminates in a sloping but fairly well-defined inflection at  $m = 7.00$ . This system is at first heterogeneous since HQS is only slightly soluble in aqueous solution and remains as a precipitate in strong acid solution. It dissolves slowly as base is added and finally disappears completely at  $m = 4.9$  ( $-\log [H^+] = 3.3$ ). Continuation of the potentiometric titration yields a good inflection at 7.00 equiv of base per U(IV) ion. Also, no white colloidal precipitate similar to that of the 1:1 U(IV)-NTA system is noted at any time during the titration. Thus, in the lower buffer region the 1:1:1 mixed ligand chelate which is initially formed is replaced by the 1:1:2 U(IV)-NTA-HQS mixed ligand chelate. Color changes noted in the lower buffer region during the titration are consistent with the formation of these mixed ligand chelate species. The final mixed ligand chelate is stable up to  $-\log [H^+] = 7.1$  where a hydroxo complex begins to form, as indicated by a drifting of  $-\log [H^+]$  values above 7.1.

**U(IV)-NTA-CS, U(IV)-NTA-IMDA, U(IV)-NTA-SSA.** The potentiometric curves of systems containing a 1:1:2 molar ratio of U(IV), NTA, and secondary ligand do not provide sufficient information to establish the existence of mixed ligand chelates. In these cases the composite curves formed by the horizontal addition of the 1:1 U(IV)-NTA curve with the free ligand curves closely approximate the experimental curves. Therefore, mixed ligand chelate formation cannot be established from the potentiometric data. Nonformation of mixed ligand chelates in the cases of the 1:1:2 U(IV)-NTA-CS and U(IV)-NTA-IMDA systems is indicated by the fact that a colloidal precipitate of a hydroxo species is present from the start of the titration. This is similar to the precipitate noted in the case of the 1:1 U(IV)-NTA chelate. However, it should be pointed out that weak mixed ligand chelates may be formed during the initial stages of the titration. However, these species are not detectable with the experimental methods employed in the present study.

**U(IV)-NTA-Tiron.** The mixed ligand potentiometric curve (Figure 3, curve C) for a 1:1:2 molar ratio of U(IV), NTA, and Tiron has a buffer region at low  $-\log [H^+]$  values with a poorly defined inflection at  $m = 4.50$ . Beyond this inflection drifting is noted at and beyond  $m = 4.70$  ( $-\log [H^+] = 4.3$ ), showing that hydrolysis and ololation reactions may take place in this region. A similar inflection at  $m = 4.50$  was noted previously by Carey, *et al.*,<sup>5</sup> for the 1:1:2 Th(IV)-NTA-Tiron system and was found to have been caused not by the formation of a mixed ligand chelate, but by the simultaneous formation of two distinct simple chelates  $Th(NTA)_2^{3-}$  and  $Th_2(Tiron)_2^{4-}$ . The

Comparison of Formation Constants of Mixed Ligand Chelates from the 1:1 Chelates and Th(IV) with EDTA ( $H_4L^{4-}$ ) and 1 Mole of an Additional Ligand ( $H_nA$ ) [ $25^\circ$ ,  $\mu = 0.10$  (KCl)]

complex has been described by Murakami and [10, 11]

In order to determine if a similar explanation applies to the 1:1:2 U(IV)-NTA-Tiron system, a potentiometric curve was run employing the correct stoichiometric amounts of U(IV) and Tiron. The resulting curve yielded a potentiometric titration (Figure 3, C) with a low buffer region and a poor slope. The inflection at  $m = 3.00$ . Color changes are also observed, coupled with the inflection at  $m = 3.00$ , indicating that a 1:1.5 U(IV)-Tiron complex, similar to the (Tiron)<sub>2</sub> complex, is probably formed initially. It has been shown previously<sup>9</sup> that 1 mole of U(IV) reacts with 2 moles of NTA to give an extremely stable 1:2 U(IV)-NTA complex which yields a curve with an inflection at  $m = 6.00$ . Thus in the 1:1:2 U(IV) ligand system half of the U(IV) combines with the NTA present in the solution giving the 1:2 U(IV)-NTA complex, while the other half of the U(IV) combines with the Tiron giving the U<sup>IV</sup>(Tiron)<sub>2</sub> complex. Thus at  $m = 4.5$ , the solution is  $1 \times 10^{-3} M$  in the 1:2 U(IV)-NTA complex,  $0.5 \times 10^{-3} M$  in the U(IV)-Tiron complex, and  $2.50 \times 10^{-3} M$  in excess Tiron.

In order to verify this interpretation two additional experiments were measured potentiometrically: a solution  $10^{-3} M$  in the 1:2 U(IV)-NTA chelate (Figure 3, B) that gave an inflection at  $m = 6.0$ , and a 1:4 U(IV)-Tiron solution  $1.0 \times 10^{-3} M$  in U(IV) (Figure 3, A) that gave an inflection at  $m = 3.00$ . The difference of the ordinates of these two curves yields a curve which is superimposable on the actual experimental curve beyond the inflection at  $m = 4.5$ . This gives convincing evidence that in the lower buffer region what is occurring is the formation of the two species U<sup>IV</sup>(NTA)<sub>2</sub><sup>2-</sup> and U<sup>IV</sup>(Tiron)<sub>2</sub><sup>4-</sup> rather than a mixed ligand chelate. This conclusion is also supported by color changes in the solution during the titration. The general sequence of reactions in this ligand system may be summarized as

where NTA =  $H_4L$  and Tiron =  $H_2A^{2-}$ . Finally, drifting indicating hydrolysis is noted at and beyond  $-\log [H^+] = 4.3$  ( $m = 4.6$ ) for the 1:1:2 system, as expected, since these conditions are the same as those under which hydrolysis occurs for the 1:4 and 1:1.5 U(IV)-Tiron systems.

**Equilibrium Constants.** The formation constants for the combination of 1 mole of a secondary ligand with the U(IV)-EDTA chelate compound are given in Table I.

## Discussion

The present work on mixed ligand U(IV) chelates, as well as the previous study of mixed ligand chelates of Th(IV),<sup>5</sup> leads to a logical classification of reaction systems containing two different ligands into the following basic types (L represents a "primary" ligand and A represents a "secondary" ligand, and ionic charges are omitted for clarity).

1. Combination of the metal ion with both ligands simultaneously to form a mixed ligand chelate in a single step.

2. Formation of a mixed ligand chelate in two overlapping steps reflecting slight differences in the affinities of the ligands for the metal ion.

3. Formation of a mixed ligand chelate in two distinctly separated steps, reflecting a large difference in the affinity of the ligands for the metal ion.

4. Formation of a mixture of two simple chelate compounds rather than a mixed ligand chelate.

5. A simple complex is formed between one ligand and the metal ion while the other ligand remains unbound in the solution.

All the above five types may be further subdivided according to whether the mixed complex or simple

complex once formed is resistant (class A) or susceptible (class B) toward hydrolysis. It should be understood that the above is not intended to be an exhaustive classification system, but merely one which covers the reaction types of various mixed ligand chelate systems that have been observed thus far.

**Mixed Ligand Chelates of EDTA.** Table II summarizes the evidence for mixed ligand chelate systems of EDTA. It should be noted that the reactions listed may be classified as 2A or 2B, the one exception being the 1:1:1 U(IV)-EDTA-PY system, which is classified as 3B. Mixed ligand complexes are formed by all of the secondary ligands investigated, and the mixed complexes once formed are quite stable. In cases where the secondary ligand contains an aromatic hydroxyl group, the high stabilities of the mixed ligand chelates is evidenced by the lack of hydroxo complex formation in the case of the 1:1:1 U(IV)-EDTA-Tiron chelate, and the high pH at which hydroxo complex formation is observed in the other systems.

**Table II.** Mixed Ligand Complexes Formed from U(IV)-EDTA (UL) [25°,  $\mu = 0.10$  (KCl)]

Ligand added	Inflection <sup>a</sup>	Species formed	Hydroxo complex formation	Reaction type
None	2, 3	UL, ULOH <sup>-</sup> (ULOH) <sub>2</sub> <sup>2-</sup>	pH > 4.0	..
Tiron (H <sub>2</sub> A <sup>2-</sup> )	4	ULA <sup>2-</sup>	None	2A
CS (H <sub>2</sub> A <sup>2-</sup> )	4	ULA <sup>2-</sup>	pH > 9.4	2B
PY (H <sub>2</sub> A)	2, 4	ULA <sup>2-</sup>	pH > 10.6	3B
HQS (H <sub>2</sub> A)	4, 5	ULA <sup>2-</sup> , ULAOH <sup>2-</sup>	pH > 7.1	2B
SSA (H <sub>2</sub> A)	5	ULA <sup>2-</sup>	pH > 8.5	2B
SA (H <sub>2</sub> A)	4	ULA <sup>2-</sup>	pH > 8.5	2B
IMDA (H <sub>2</sub> A)	4	ULA <sup>2-</sup>	pH > 9.0	2B
Ph (HA <sup>-</sup> )	3	ULA <sup>2-</sup>	pH > 6.5	2B

<sup>a</sup> Numbers represent moles of base added per mole of UL.

It is of interest to consider the equilibrium constants for the formation of the mixed ligand chelates, listed in Table I, from the point of view of the constitution of the added ligand. It is seen that CS forms the most stable mixed ligand chelate of all the compounds listed and that the corresponding Tiron complex has nearly the same stability, while the affinity of the catecholate anion for the U(IV)-EDTA chelate is slightly lower. The fact that these stabilities are much higher than any of the other values listed in Table I may be rationalized on the basis that, of the donor groups investigated, the phenoxide groups have the highest affinity for the U(IV) ion. The Tiron and chromotropic salt data are also interesting as an indication that under certain conditions a six-membered chelate ring may be more stable than an analogous five-membered ring.

Two other ligands, HQS and SSA, which provide one phenoxide ion each, form mixed ligand chelates which are somewhat less stable, but nevertheless still appear quite high in the sequence of relative stabilities. In accordance with these observations the least stable mixed ligand chelates are those which are formed from secondary ligands (IMDA and Ph) having primarily carboxylate groups as electron donors.

Table III summarizes the results for mixed ligand chelates of NTA. The first three examples listed are

seen not to involve mixed ligand chelate formation hence these systems belong to class 5B. It is noted that hydroxo complex formation is first observed in a few cases around the same low pH where hydroxo complex formation of the U(IV)-NTA chelate itself occurs. This observation supports the argument that no mixed ligand complex is formed. In the case of HQS, however, the fact that hydroxo complex formation takes place at a higher pH than that at which the 1:1 U(IV)-NTA chelate hydrolyzes is evidence for mixed ligand chelate formation.

**Table III.** Mixed Ligand Complexes Formed from U(IV)-NTA (UL<sup>+</sup>) [25°,  $\mu = 0.10$  (KCl)]

Ligand added	Inflection <sup>a</sup>	Species formed	Hydroxo complex formation
None	~4.75	Hydrolysis product of UL <sup>+</sup>	pH > 2.5
CS (H <sub>2</sub> A <sup>2-</sup> )	~4.8, ~6.75	None	pH > 2.5
SSA (H <sub>2</sub> A)	~8.75	None	pH > 3.0
IMDA (H <sub>2</sub> A)	~6.70	None	pH > 2.2
HQS (H <sub>2</sub> A)	7.00	ULA <sup>2-</sup> , ULA <sub>2</sub> <sup>2-</sup>	pH > 7.1
Tiron (H <sub>2</sub> A <sup>2-</sup> )	4.50	ULA <sup>2-</sup> , U <sub>2</sub> A <sub>2</sub> <sup>4-</sup>	pH > 4.3

<sup>a</sup> Numbers indicate moles of base added per mole of UL.  
<sup>b</sup> Weak mixed ligand complexes may be formed initially.

Finally, as discussed in detail above, the U(IV)-NTA-Tiron system (reaction type 4B) is unique when compared to all the other systems studied. The high stabilities of the individual single-ligand chelates are such that the mixed ligand chelate is not formed to a detectable extent.

**Coordination Number of U(IV).** It has been noted in the present investigation that in the great majority of the mixed ligand chelates studied, the U(IV) seems to have an effective coordination number of eight. Hence, the resulting U(IV) mixed ligand complexes will probably have dodecahedral arrangements of donor groups similar to that shown by A in Figure 1 for the 1:1:1 U(IV)-EDTA-Tiron complex.

However, the 1:1:1 U(IV)-EDTA-IMDA system indicates the possibility of the expansion of the coordination number of U(IV) from a value of eight to that of nine. Formation of an EDTA-IMDA mixed ligand chelate may be interpreted as involving the displacement of one of the carboxylate groups of EDTA to make way for the three donor groups of IMDA, keeping the total coordination of U(IV) at eight. On the other hand, the relatively high stability constant for the addition of IMDA argues in favor of expansion of the coordination number of U(IV) to nine. In the 1:1:1 U(IV)-EDTA-IMDA mixed ligand chelate, it would probably involve nonacoordination of U(IV) in aqueous solution, as is indicated by Figure 4B. Although no structural data are available for U(IV) coordination in solution, the trigonal prismatic +3 structure suggested<sup>14</sup> seems to offer the most favorable reduction in mutual repulsions between the negative carboxylate donor groups of the ligand and a reasonable arrangement of the metal chelate rings. The most stable 1:1:1 monohydroxo U(IV)-EDTA-HQS system

(14) A. F. Wells, "Structural Inorganic Chemistry," 3rd ed., Clarendon Press, New York, N. Y., 1962, pp 98-100.

so involve similar nonacoordination of U(IV). postulated expansion of the coordination number (V) to nine for the 1:1:1 U(IV)-EDTA-IMDA. The 1:1:1 monohydroxo U(IV)-EDTA-HQS ligand chelate is similar to expansion of the coordination number of Th(IV) from eight to nine in the 1:1:1 Th(IV)-EDTA-IMDA and 1:1:1 Th(IV)-EDTA-NTA mixed ligand chelates postulated by Carey, *et al.*<sup>5</sup> Also, possible expansion of the U(IV) coordination number from eight to a higher value was previously noted by the present authors<sup>9</sup> for the monohydroxo 1:1 U(IV)-DTPA chelate and the 1:1 U(IV)-TTHA chelate (where DTPA is diethylenetriamine-pentaacetic acid and TTHA is triethylenetetramine-pentaacetic acid).

Equilibrium constants for the formation of mixed chelates of U(IV) from the U(IV)-EDTA chelate compared in Table I with those of the analogous Th(IV) chelates previously reported by Carey, *et al.*<sup>5</sup> In the mixed ligand systems studied there is the expected increase in formation constants when Th(IV) is replaced by U(IV) in the mixed ligand chelate. This increased stability is due to the smaller radius of the U(IV) ion, which results in more favorable  $\Delta H$  and  $\Delta S$  effects. The favorable enthalpy effect is due to the stronger ionic bond strength of U(IV) complexes.

In addition, there will also be a favorable entropy effect since the smaller U(IV) chelate of the primary ligand will be more strongly hydrated in solution than the corresponding Th(IV) chelate. Consequently, reaction with the secondary ligand to form the 1:1:1 U(IV) mixed ligand chelate results in a greater entropy increase due to displacement of coordinated water molecules which occurs with the analogous Th(IV) chelate.

Figure 4. (A) Eight-coordinated 1:1:1 U(IV)-EDTA-Tiron mixed ligand chelate; (B) nine-coordinated 1:1:1 U(IV)-EDTA-IMDA mixed ligand chelate.

Table I also shows that the formation of the monohydroxo mononuclear mixed ligand chelate from the 1:1:1 Th(IV)-EDTA-HQS mixed ligand chelate occurs more readily when the Th(IV) ion is replaced by the U(IV) ion. This may also be considered to be principally a consequence of the smaller radius of the U(IV) ion.

# Electron-Transfer Complexes of the $[M-N_2S_2]$ Type. The Existence of Cation-Stabilized Free-Radical Complexes

R. H. Holm,<sup>1a</sup> A. L. Balch,<sup>1b</sup> A. Davison,<sup>2</sup> A. H. Maki,<sup>3a</sup> and T. E. Berry<sup>3a,b</sup>

Contribution from the Departments of Chemistry, University of Wisconsin, Madison, Wisconsin, Massachusetts Institute of Technology, Cambridge, Massachusetts, and University of California, Riverside, California. Received January 3, 1967

**Abstract:** The propensity to undergo chemical and electrochemical one-electron-transfer reactions, already established in bis-chelate complexes of the general types  $[M-S_4]^+$  and  $[M-N_4]^+$ , has been shown to extend to two groups of  $[M-N_2S_2]^+$  complexes. The first group consists of bis-chelate species of presumed *trans* structure and is exemplified by bis(*o*-mercaptoanilido)nickel,  $Ni[o-C_6H_4(NH)S]_2$ , which undergoes two one-electron reductions in DMSO and dichloromethane solutions and one one-electron oxidation in dichloromethane solution. The mono anion ( $z = -1$ ) of this four-member electron-transfer series has a doublet ground state and displays in glasses a markedly anisotropic  $g$  tensor, similar to those of  $[Ni-S_4]^-$  and  $[Ni-N_4]^-$  species, and, accordingly, is assigned a  $^2B_g$  ground state with an appreciable admixture of metal orbital in the odd-electron wave function. The second group is composed of tetradentate complexes having a necessarily *cis*- $N_2S_2$  arrangement. Complexes of the types  $M(gma)^+$ ,  $M(dtbh)^+$ , and  $Ni(dbh)^+$  were obtained with  $M = Ni, Cu, Zn, Cd$  ( $gma$  = glyoxalbis(*o*-mercaptoanil),  $dtbh$  = biacetylbis(thiobenzoylhydrazone),  $dbh$  = biacetylbis(benzoylhydrazone)). The  $Ni, Zn$ , and  $Cd$  neutral complexes are electrochemically reducible in nonaqueous media to  $z = -1$  and  $-2$  species. The monoanions possess doublet ground states. Their  $g$  tensors reveal a barely noticeable but unresolvable anisotropy ( $Ni$ ) or no observable anisotropy ( $Zn, Cd$ ). Because the  $Zn^-$  and  $Cd^-$  species can only be reasonably formulated as cation-stabilized free radicals (csfr), the properties of their  $g$  tensors are proposed as reasonable criteria for the appropriateness of csfr formulations, at least in  $[M-S_4]^+$ ,  $[M-N_4]^+$ , and  $[M-N_2S_2]^+$  systems. The epr properties of the *cis*- $[M-N_2S_2]^+$  complexes are interpreted in terms of a simple qualitative molecular orbital model, and probable ground states are assigned to five isoelectronic series of complexes of this general type.

The original demonstration<sup>4</sup> of the interrelationship of certain bis(*cis*-1,2-disubstituted ethylene-1,2-dithiolato) complexes (1) by electron-transfer reactions has been followed by extensive synthetic and physical investigations of these and related complexes.<sup>5</sup> Research in this area has taken two general directions. The first relates to the scope of electron-transfer reactions. It has been shown that neither an ethylenic ligand backbone nor an  $S_4$  coordination sphere is a necessary condition for electron-transfer reactions because the complexes 2 (including ring-substituted variants)<sup>6</sup> and 3, having  $X = Y = O$ ,<sup>7</sup>  $X = Y = NH$ ,<sup>8</sup> and  $X = O, Y = S$ ,<sup>9</sup> undergo one or more such reactions. The presence of a five-membered delocalized chelate ring does appear to be required, however.<sup>10</sup>

The second research direction has been toward an elucidation of the ground- (and excited-) state descriptions of these complexes. Nearly all investigations have centered about the  $[NiS_4C_4R_4]^-$  species, which have rich electronic spectra and doublet ground states. Their paramagnetic resonance spectra are readily observable in both fluid and glassy media, thereby permitting measurements of the isotropic  $g$  value and the principal components of the  $g$  tensor.

Among the essential features of any ground-state description in current molecular orbital theory are (i) specification of the symmetry of the highest occupied MO and, therewith, the possible metal and ligand orbitals admixed; and (ii) an estimate of the composition of this MO in terms of metal and ligand contributions. Of all nickel monoanions,  $Ni(mnt)_2^-$  (1,  $R = CN$ ) has been the most thoroughly studied.<sup>11,12</sup> Measurement of the spin-Hamiltonian parameters of this ion enriched in  $^{61}Ni$  in an oriented, magnetically dilute, single crystal has led to the conclusion that the most probable ground-state configuration is  $\dots b_{2g}^{-1} b_{1g}^0$  and that the  $b_{2g}$  MO<sup>13</sup> has, very roughly, 50% metal character.<sup>11,15</sup> Application of semiempirical

(13) Note that the defined  $x$  and  $y$  axes in  $D_{2h}$  symmetry are interchanged in ref 11 compared to ref 12 and 14; we refer to the axis system of ref 11 in which the origin is at the metal, the  $xy$  plane is that of the complex, and the  $y$  axis bisects the chelate rings. Thus the  $d_{xy}$  orbital has  $b_{2g}$  symmetry.

(15) The most probable ground state was deduced by the best fit of the measured principal components of the  $g$  and  $A(^{61}Ni)$  tensors to theoretical expressions for these quantities calculated using perturbation theory and a basis set of pure metal 3d functions.<sup>11</sup> The use of this basis set has been criticized and the statement made that the epr results

ory has led to two different ground states for  $[\text{Ni}(\text{mnt})_2]^-$ . Shupack, *et al.*,<sup>12</sup> claim a  $^2A_{1g}(\dots)$  state and 26% metal character for the  $a_{1g}[\text{Ni}(\text{mnt})_2]^-$ . It is difficult to reconcile this state with the observed spin-Hamiltonian parameters.<sup>11</sup> Schrauzer and Mayweg<sup>14</sup> report calculation for the magnetically similar ion,  $[\text{NiS}_4\text{C}_4\text{H}_4]^-$ , to a likely  $^2B_{2g}(\dots b_{2g}^1 b_{1g}^0)$  ground state and metal character in the  $b_{2g}$  MO. Because spin-orbital parameters are the most demanding for metal complexes to be reconciled with their electronic properties, we feel that the designation of  $[\text{Ni}(\text{mnt})_2]^-$  as containing, in a purely formal sense,  $\text{Ni}(\text{III})$  with the attendant  $d^7$  configuration is reasonable and is the preferred formulation for interpreting epr properties.

Our formulation for  $[\text{Ni}(\text{mnt})_2]^-$ , in conjunction with the  $A_{1g}$  ground state, has been put forth.<sup>12</sup> This formulation involves  $\text{Ni}(\text{II})$  with the odd electron delocalized on the ligands. Such a complex could be considered a cation-stabilized free radical (csfr). In covalent complexes such as those considered in this paper, a ground-state description in terms of a formal oxidation state of the metal (and, hence, of the ligands) is not a designation cannot be precise and must be an approximation, for both represent extreme cases. This point is well emphasized by  $[\text{Ni}(\text{gma})]^-$ , the initial product of glyoxalbis(*o*-mercaptoanil)nickel,  $[\text{Ni}(\text{gma})]^-$  (4,  $z = 0$ ). Authentic  $[\text{Ni}(\text{gma})]^-$  exhibits a detectable but rather small  $g$ -tensor anisotropy<sup>19</sup> and does not lend itself to either description inadequate. Obviously, what is needed is a complete MO description of the ground state for this and the other complexes considered. Because MO theory in its present semi-empirical form cannot be considered reliable in predicting ground states for species of the complex 1-4, we feel that it is useful to establish criteria for the application of the limiting descriptions. Accordingly, we report here our efforts to establish epr criteria for detectable involvement or lack of essential

interpreted in terms of a complete MO basis set" is on the basis of the metal-ligand bonding is rather covalent<sup>13</sup> (*vide supra*). This statement is the contention that if a complete basis set is used, a ground-state description might emerge from the process of diagonalizing  $g$  and  $A$  components using precalculated MO's of the complex. We suggest that it is unrealistic to assume that eigenvalues can be calculated so accurately by semiempirical procedures for subsequent use, together with calculated or observed energy levels, can generate  $g$  and  $A$  values of sufficient validity to justify a more certain ground-state assignment than that made from a limited basis set. Covalency has been introduced in connection with the use of a limited basis set by reasonable reduction of parameters in fitting measured parameters to theory.<sup>11</sup> The use of epr data involves the evaluation of metal-ligand mixtures from measured  $g$  and  $A$  values (*cf.*, e.g., A. H. Maki and R. E. Orville, *J. Chem. Phys.*, **29**, 31 (1958); H. R. Gersmann and R. E. Orville, *ibid.*, **36**, 3221 (1962)) rather than the calculation of these parameters from preconstructed MO's of the complex. Finally, either a semi-empirical or a molecular orbital approach to the complexity of the problem is a formidable task for molecular species of the complexity of the complexes considered. In our previous work we have preferred to use the epr tractable form.

J. Stiefel, J. H. Waters, E. Billig, and H. B. Gray, *J. Am. Chem. Soc.*, **87**, 3016 (1965).

Adamus, Q. Fernando, and H. Freiser, *ibid.*, **86**, 3056 (1964). Results already presented,<sup>19</sup> reinforced by more recent work (F. Lalor, M. F. Hawthorne, A. H. Maki, A. Davison, and Z. Dori, and E. I. Stiefel, to be published), have convinced us that the anion with a decidedly anisotropic  $g$  tensor produced by borohydride reduction of  $[\text{Ni}(\text{gma})]^-$  was incorrectly identified as  $[\text{Ni}(\text{gma})]^-$  in ref 16 and that the sodium amalgam product (see Experimental Section) is actually  $[\text{Ni}(\text{gma})]^-$ , as ref 19.

A. Maki, T. E. Berry, A. Davison, R. H. Holm, and A. L. Balch, *Chem. Soc.*, **88**, 1080 (1966).

involvement of metal orbitals in the wave functions of unpaired electrons in complexes of the types 1-4. As part of this work the electron-transfer properties of complexes of the type  $[\text{M}-\text{N}_2\text{S}_2]$  have been investigated. The results augment those already obtained for  $[\text{M}-\text{S}_4]$ ,<sup>6</sup>  $[\text{M}-\text{O}_4]$ ,<sup>7</sup>  $[\text{M}-\text{N}_4]$ ,<sup>8</sup> and  $[\text{M}-\text{O}_2\text{S}_2]$ <sup>9</sup> systems in which, principally,  $\text{M} = \text{Ni}$ . Certain of our results on gma complexes have been communicated in preliminary form.<sup>19</sup>

## Experimental Section

**Preparation of Compounds.** (a) **Glyoxalbis(*o*-mercaptoanil) Complexes,  $[\text{M}(\text{gma})]^-$ .**  $\text{Zn}(\text{gma})$  and  $\text{Cd}(\text{gma})$  were prepared according to a published procedure.<sup>17</sup>  $[\text{Ni}(\text{gma})]^-$  was obtained in an entirely analogous manner as shiny black crystals only sparingly soluble in most organic solvents. A freshly prepared sample was analyzed.

*Anal.* Calcd for  $\text{C}_{14}\text{H}_{10}\text{N}_2\text{S}_2\text{Ni}$ : C, 51.09; H, 3.06; N, 8.51; S, 19.49. Found: C, 51.20; H, 3.27; N, 8.22; S, 19.53.

$[(n\text{-C}_4\text{H}_9)_4\text{N}][\text{Ni}(\text{gma})]$ . The following operations were performed in *vacuo* or in a nitrogen atmosphere. A suspension of 3.6 g (0.012 mole) of  $[\text{Ni}(\text{gma})]^-$  in 30 ml of dry, peroxide-free tetrahydrofuran was shaken with a dilute amalgam made from 0.23 g (0.010 g-atom) of sodium and 25 ml of mercury. A rapid reaction with heat evolution ensued to produce an intense red-brown solution, which was separated from the amalgam and filtered to remove unreacted, excess  $[\text{Ni}(\text{gma})]^-$ . The filtrate was treated with a solution of 3.5 g of tetra-*n*-butylammonium bromide in 300 ml of methanol. Agitation of the solution caused the product to separate as small needles during a 2-3-min period. It was collected by filtration and washed with methanol (three 20-ml portions). The product was dried at 25° (10<sup>-3</sup> mm) for 10 hr and obtained as small, shiny, black crystals, soluble in polar organic solvents to give red-brown solutions. Oxidation of these solutions by air yields immediately  $[\text{Ni}(\text{gma})]$ .

*Anal.* Calcd for  $\text{C}_{20}\text{H}_{14}\text{N}_2\text{S}_2\text{Ni}$ : C, 63.05; H, 8.11; N, 7.35; S, 11.22. Found: C, 61.93, 61.83; H, 7.65, 7.83; N, 7.22, 7.07; S, 11.36, 11.55.

In this preparation it is important to note that a deficiency of sodium was used in the reduction. Excess sodium in the amalgam gives an emerald green solution, which is easily oxidized to a red-brown solution of  $[\text{Ni}(\text{gma})]^-$  and which presumably contains  $[\text{Ni}(\text{gma})]^-$ , whose existence is indicated by polarographic data (*cf.* Table I).

(b) **Bis(*o*-mercaptoanilido)nickel.** *o*-Mercaptoaniline (5.0 g) and 2.2 g of potassium hydroxide were dissolved in 100 ml of 20% aqueous ethanol. This solution was mixed with one prepared from 4.7 g of nickel chloride hexahydrate and 15 ml of concentrated aqueous ammonia in 75 ml of water. A yellow precipitate of bis(*o*-aminothiophenolato)nickel(II) formed immediately and was filtered off. The precipitate was suspended in 300 ml of water containing 4.0 g of potassium hydroxide; air was passed through the suspension for 5 hr. The deep blue solid which formed was collected by filtration, washed with water, and dried *in vacuo* over  $\text{P}_2\text{O}_5$ . The final product was obtained by two Soxhlet extractions with diethyl ether, which yielded deep blue crystals. A very similar procedure has been used by Hieber and Brück<sup>20</sup> to prepare a blue solid which they claimed to have the composition  $[(\text{C}_6\text{H}_4(\text{NH}_2)\text{S})_2\text{Ni}]_n$ .

*Anal.* Calcd for  $\text{C}_{24}\text{H}_{18}\text{N}_4\text{O}_2\text{S}_4\text{Ni}$ : C, 44.61; H, 3.75; N, 8.67; S, 19.85; Ni, 18.17. Calcd for  $\text{C}_{15}\text{H}_{10}\text{N}_2\text{S}_2\text{Ni}$ : C, 47.25; H, 3.30; N, 9.18; S, 21.02; Ni, 19.25. Found: C, 46.79; H, 3.71; N, 9.22; S, 21.02; Ni, 19.06 (total, 99.80).

(c) **Diacetylthiothiobenzoylhydrazide Complexes  $[\text{M}(\text{dtbh})]$ .** The free ligand,  $\text{H}_2\text{dtbh}$ , and the nickel and copper complexes were obtained by the procedures of Bähr and Schleitzer.<sup>21</sup>

<sup>a</sup> All potentials not strictly comparable; see Experimental Section. <sup>b</sup>  $Cu(dtbbh)$  shows poorly resolved wave in  $CH_2Cl_2$  at  $\sim -0.49$  v ( $i_d/C \sim 19$ )

**$Zn(dtbbh)$ .** Biacetylthiobenzoylhydrazine (1.8 g) dissolved in 400 ml of ethanol was added to a solution of 1.1 g of zinc acetate dihydrate in 100 ml of ethanol. The solution volume was reduced to  $\sim 100$  ml whereupon orange crystals separated. These were collected by filtration, recrystallized twice from 1:1 v/v chloroform-ethanol, and dried over  $P_2O_5$  in *vacuo* at  $80^\circ$ . The purified product was isolated as reddish orange crystals.

*Anal.* Calcd for  $C_{18}H_{14}N_4S_2Zn$ : C, 51.74; H, 3.86; N, 13.41; S, 15.35. Found: C, 51.40; H, 3.99; N, 13.14; S, 15.05.

**$Cd(dtbbh)$ .** A solution of 1.64 g of sodium acetate trihydrate and 3.44 g of cadmium bromide tetrahydrate in 60 ml of ethanol was prepared and filtered to remove sodium bromide. To this solution was added a boiling solution of 3.53 g of biacetylthiobenzoylhydrazine in 200 ml of ethanol. The resultant deep red precipitate was collected and washed with ethanol. Purification was effected by Soxhlet extraction with chloroform followed by drying at  $80^\circ$  in *vacuo*. A brick red microcrystalline product was obtained.

*Anal.* Calcd for  $C_{18}H_{14}N_4S_2Cd$ : C, 46.50; H, 3.47; N, 12.05. Found: C, 46.84; H, 3.44; N, 12.44.

**(d) Bis(thiobenzoylhydrazide)nickel.** A solution of 2.0 g (13 mmol) of thiobenzoylhydrazine<sup>23</sup> in 100 ml of ethanol was added to a solution of 1.6 g (6.7 mmol) of nickel chloride hexahydrate in 100 ml of ethanol. Addition of 80 ml of concentrated aqueous ammonia produced a beige precipitate. The mixture was stirred for 9 hr while air was passed through it. The resulting deep blue solid was collected by filtration, washed with ethanol, and vacuum dried; the yield of the crude product is 2.0 g (80%). One gram of this material was extracted with 150 ml of pure, dry tetrahydrofuran for 8 hr. Cooling of the solution afforded a deep blue, finely crystalline product which was collected and vacuum dried.

*Anal.* Calcd for  $C_{14}H_{12}N_4S_2Ni$ : C, 46.82; H, 3.37; N, 15.60; S, 17.86. Found: C, 46.79; H, 3.17; N, 15.41; S, 17.62.

**(e) Biacetylthiobenzoylhydrazide) Complexes,  $M(dbbh)$ .** The free ligand,  $H_2dbb$ , was prepared by dissolving 14.1 g (0.10 mole) of benzoylhydrazine and 4.4 g (0.05 mole) of biacetyl in 150 ml of 1-propanol, followed by refluxing for 6 hr. The solution was filtered when hot and the white microcrystalline product washed with ethanol and ether, mp  $280-290^\circ$  dec; lit.<sup>22</sup>  $286^\circ$ .

**$Ni(dbbh)$ .** This compound was prepared according to Sacconi's method.<sup>24</sup>

**$Cu(dbbh)$ .** A solution of 3.3 g of biacetylthiobenzoylhydrazide and 0.8 g of sodium hydroxide in 70 ml of ethanol was added with stirring to a solution of 1.7 g of cupric chloride dihydrate in 50 ml of ethanol. The solution was allowed to stand for 1 hr after which brown crystals were isolated by filtration and dried. The crude product was twice recrystallized from 1:1 v/v chloroform-ethanol to yield greenish brown crystals which were dried over  $P_2O_5$  in *vacuo* at  $60^\circ$ .

*Anal.* Calcd for  $C_{18}H_{14}N_4O_2Cu$ : C, 56.32; H, 4.20; N, 14.59. Found: C, 55.92; H, 4.31; N, 14.36.

**$Zn(dbbh)$ .** This complex was prepared by the same procedure used for the cupric complex with the substitution of zinc acetate for cupric chloride. The final product was obtained as fine yellow crystals.

*Anal.* Calcd for  $C_{18}H_{14}N_4O_2Zn$ : C, 56.05; H, 4.18; N, 14.53. Found: C, 55.42; H, 4.28; N, 14.01.

**Physical Measurements.** Polarographic data were obtained using an ORNL Model 1988 polarograph equipped with a three-electrode configuration. A rotating platinum electrode served as the working electrode. For measurements in acetonitrile and 0.05 M ( $n$ -Pr)<sub>4</sub>NClO<sub>4</sub> supporting electrolyte were employed. In dichloromethane solutions the supporting electrolyte was 0.1 M ( $n$ -Bu)<sub>4</sub>N(PF<sub>6</sub>) and potentials were measured vs. a Ag-AgI reference electrode immersed in a 0.05 M ( $n$ -Bu)<sub>4</sub>NI-0.5 M ( $n$ -Bu)<sub>4</sub>N-PF<sub>6</sub> solution in dichloromethane. The sample and reference compartments were connected by a salt bridge of silica gel impregnated with a dichloromethane solution of the supporting electrolyte. The entire arrangement for measurements in dichloromethane is described in detail elsewhere.<sup>7</sup> The potentials quoted in Table I were obtained from measurements of solutions prepared from the neutral complexes. Electron paramagnetic resonance measurements were made using a Varian V-4500 spectrometer with 100-kc/sec field modulation. The klystron frequency was measured by means of a transfer oscillator and frequency counter, and the magnetic field was measured with a proton resonance gaussmeter monitored by the same frequency counter.

## Results and Discussion

Polarographic and epr results referred to in the following sections are set out in Tables I-III.

**Electron-Transfer Properties of  $[M-N_2S_2]^+$  Complexes.** The possibility that complexes of this general type have electron-transfer properties was stimulated by the report of Hieber and Brück<sup>20</sup> that a deep blue product resulted from the reaction of bis(*o*-aminothiophenolato)nickel(II) with oxygen in basic solution. Earlier, Feigl and Fürth<sup>25</sup> had reported a very similar reaction of a nickel salt and *o*-phenylenediamine in aqueous ammoniacal solution which led to a deep blue product now known to have the formulation  $Ni[o-C_6H_4(NH)_2]_2$  and to be the central member of a five-membered electron-transfer series.<sup>8</sup> An entirely analogous series, based on similar reasoning,<sup>7,8</sup> can be envisaged for the  $[Ni-N_2S_2]^+$  system consisting of the members 5-9. The Hieber-Brück product was claimed by them to have the composition  $NiO[C_6H_4(NH_2)S]_2$  and the dimeric  $\mu, \mu'$ -dioxo-bridged structure 10; this formulation has been widely quoted in standard texts and references as one of the few Ni(IV) complexes. As communicated earlier,<sup>7</sup> repetition of this preparation<sup>20</sup> leads to a deep blue, diamagnetic compound whose *total* analysis corresponds to the composition  $Ni[o-C_6H_4(NH)_2]_2$ .<sup>26</sup> That

<sup>a</sup> Complex reduced (where appropriate) by method given in column 3. <sup>b</sup> Mixed solvents are 50-50 v/v. <sup>c</sup> cpe, controlled potential electrolysis;  $\text{Na}(\text{Hg})$ , 2% sodium amalgam. <sup>d</sup> Isotropic (solution) values; parentheses indicate value calculated from glass data. <sup>e</sup> Calculated from  $\langle g \rangle$  and  $g_{11}$ . <sup>f</sup> Fresh solution measured. <sup>g</sup> Reduction with borohydride in THF yields  $\text{Ni}(\text{H}_2\text{gma})^-$ , data from ref 18. <sup>h</sup> No measurable anisotropy in glass; spectra show additional line and half-field resonance compatible with triplet species. <sup>i</sup> Anisotropy not resolvable, measurement made at center of absorption. <sup>j</sup>  $\langle \alpha(^{63}\text{Cu}) \rangle = 7.19 \times 10^{-3} \text{ cm}^{-1}$ ,  $\langle \alpha(^{14}\text{N}) \rangle = 1.13 \times 10^{-3} \text{ cm}^{-1}$ ,  $a_{11}(^{63}\text{Cu}) = 1.68 \times 10^{-3} \text{ cm}^{-1}$ ,  $a_{11}(^{14}\text{N}) = 1.37 \times 10^{-3} \text{ cm}^{-1}$ . <sup>k</sup>  $\langle \alpha(^{63}\text{Cu}) \rangle = 8.18 \times 10^{-3} \text{ cm}^{-1}$ ,  $\langle \alpha(^{14}\text{N}) \rangle = 1.38 \times 10^{-3} \text{ cm}^{-1}$ .

this compound is the central member 7 of the electron-transfer series 5-9 is evidenced by the two one-electron reductions in DMSO and a (very anodic) one-electron

oxidation in dichloromethane. The most oxidized member, 9 has not been detected, probably because of the instability of the *o*-thionequinoneimine structure.

(26) The correct formulation of the Hieber-Brück product has also been recognized in reports<sup>16,17</sup> appearing shortly after our original communication.<sup>8</sup> Supporting evidence includes a parent ion peak in the mass spectrum at  $m/e$  304<sup>16</sup> and the results of a total analysis including oxygen.<sup>17</sup>

(27) L. F. Larkworthy, J. M. Murphy, and D. J. Phillips, *J. Am. Chem. Soc.*, **88**, 1570 (1966).

Despite the relative ease with which the neutral complex is reduced to the monoanion by a variety of mild reducing agents, we have been as yet unable to isolate a pure salt of this species.

The electron-transfer propensity of  $\text{Ni}(\text{gma})$  was first demonstrated by Stiefel, *et al.*,<sup>16</sup> who have shown that the series  $\text{Ni}(\text{gma})^z$  ( $z = 0, -1, -2$ ) exists. The neutral nickel complex<sup>17</sup> as well as neutral complexes of other metals,<sup>17,28</sup> including zinc and cadmium,<sup>17</sup> have been isolated. We have verified the existence of the three-membered series in DMSO and DMF by polarography and have established by cyclic voltammetry the

(28) E. Bayer, *Angew. Chem.*, **73**, 659 (1961); **76**, 76 (1964).

reversibility of the electrode reactions in DMF.<sup>19</sup> In addition, we have found that Zn(gma) and Cd(gma) in DMF and DMSO can be reduced in two reversible, one-electron steps to the mono- and dianions at potentials significantly more negative than those of the Ni(gma)<sup>+</sup> system. Reduction of Ni(gma) with sodium amalgam in tetrahydrofuran has afforded the exceedingly oxygen-sensitive monoanion as the crystalline tetra-*n*-butylammonium salt. Because of their extreme oxidative instability, no attempt has been made to isolate the zinc or cadmium mono- and dianions or the nickel dianion.

An electron-transfer series analogous to 5-9 can be visualized for the M(gma)<sup>+</sup> system. The terminal reduced member could be represented by 11 ( $z = -2$ ) and the intermediate neutral member by 4 or 11 ( $z = 0$ ) or some resonance combination thereof. The gma ligand system provides three five-membered chelate rings, each of which can be to some extent delocalized with concomitant change in formal oxidation state of the metal.<sup>20</sup> Obviously related delocalization possibilities exist in the neutral complexes of 1, 2, and 3, thereby underscoring the electronic similarities of the ligand systems known to promote electron-transfer behavior.

We have investigated the generality of electron-transfer reactions in other [M-N<sub>2</sub>S<sub>2</sub>] complexes by examining species having in principle delocalization properties analogous to those of 7 and 4 (or 11) but with otherwise dissimilar ligand systems. In this connection we have reexamined the work of Jensen and Miguel,<sup>30</sup> who have reported that a deep blue product of apparent composition Ni[SC(Ph)NNH]<sub>2</sub> results from the aerobic oxidation of an ammoniacal solution of nickel chloride and thiobenzoylhydrazine. We have obtained this product under similar conditions and confirmed its composition. The oxidation presumably proceeds through the intermediates Ni[SC(Ph)NHNH<sub>2</sub>]<sub>2</sub>Cl<sub>2</sub> and Ni[SC(Ph)NHNH]<sub>2</sub>, both of which have been isolated.<sup>30</sup> The deep blue product can be reduced polarographically in DMSO to the  $z = -1$  and  $-2$  species at potentials very similar to those of the Ni[o-C<sub>6</sub>H<sub>4</sub>(NH)S]<sub>2</sub><sup>+</sup> system. The structures of the Ni[SC(Ph)NNH]<sub>2</sub><sup>+</sup> species can be represented by 12 and other appropriate valence-bond representations.<sup>31</sup>

Biacetylbis(thiobenzoylhydrazone) complexes, one representation of which is 13,<sup>32</sup> bear the same resemblance

to Ni[SC(Ph)NNH]<sub>2</sub><sup>+</sup> as does M(gma)<sub>2</sub><sup>+</sup> to Ni[o-C<sub>6</sub>H<sub>4</sub>(NH)S]<sub>2</sub><sup>+</sup>. Accordingly, these complexes, first prepared by Bähr and Schleitzer,<sup>21</sup> do undergo electron-transfer reactions. The neutral complexes with M =

Ni, Zn, Cd may be reduced in two one-electron steps to the  $z = -1$  and  $-2$  species in DMSO. Because of the apparent instability of Ni(gma)<sup>-</sup> in at least one solvent medium,<sup>18,19</sup> we have verified the existence of the  $-1 \rightleftharpoons 0$  couple of nickel-, copper-, and zinc-dtbh complexes in three solvents. The M(dtbh)<sup>-</sup> species are considerably more oxidatively unstable than are the corresponding M(gma)<sup>-</sup> complexes, and isolation of them has not proven feasible. Cu(dtbh) is particularly easily reduced to a monoanion, but despite a number of attempts we have not been able to isolate a pure salt of this ion.

Several complexes of biacetylbis(benzoylhydrazone) have been prepared. These differ from 13 only in having oxygen in place of sulfur. Ni(dbh) undergoes two one-electron reductions in DMSO where it presumably exists as a paramagnetic, solvated species. Only the first reduction is observed in dichloromethane and acetonitrile, in which the neutral complex is diamagnetic and occurs at potentials significantly more negative than those for Ni(dtbh) in the same solvents. Cu(dbh) and Zn(dbh) do not undergo well-defined one-electron reductions.

**Epr Results.** (1) [Ni-S<sub>4</sub>]<sup>-</sup> and [Ni-N<sub>4</sub>]<sup>-</sup> Complexes. A collection of *g*-value data for all presently known anions of these types is given in Table II. It is evident that all complexes are markedly anisotropic and that isotropic and anisotropic *g* values of [NiS<sub>4</sub>C<sub>4</sub>R<sub>4</sub>]<sup>-</sup> species are virtually independent of R. It is concluded that all of these ions, including Ni[o-C<sub>6</sub>H<sub>4</sub>(NH)<sub>2</sub>]<sub>2</sub><sup>-</sup>, very probably have the same ground state although the extent of electron delocalization may differ somewhat among the species. On the basis of previous work<sup>11</sup> the probable ground state is <sup>2</sup>B<sub>g</sub>, which generates the following characteristic features in these anions:<sup>33</sup> (i) *g* equal to or in excess of 2.03 and a lower limit of ~2.05 for [Ni-S<sub>4</sub>]<sup>-</sup>; (ii) three observable principal *g* values, showing that the effective ligand field is of rhombic, not axial, symmetry. These observations do not support a pure csfr description of the ground state. Although three principal *g* values have been observed

Taylor, E. J. Gabe, J. P. Glusker, J. A. Minkin, and A. L. Patterson, *J. Am. Chem. Soc.*, **88**, 1845 (1966)). The complex is planar and is depicted as having an  $\alpha$ -diimine chelate ring; bond angles and distances were not given.

(33) An analogous ground state (<sup>2</sup>B<sub>g</sub> in C<sub>4h</sub> symmetry) applies for Ni[o-C<sub>6</sub>H<sub>4</sub>OS]<sub>2</sub><sup>-</sup> which has *g* = 2.083, *g*<sub>1</sub> = 2.017, *g*<sub>2</sub> = 2.036, *g*<sub>3</sub> = 2.191 (DMF-CHCl<sub>3</sub>),<sup>9</sup> values nearly identical with those of Ni(tdt)<sub>2</sub><sup>-</sup> in the same medium.<sup>34</sup>

(29) No X-ray structural information on gma complexes is available so that the relative contributions of 4 and 11 to the ground state of neutral complexes is unknown. The structure of the related complex biacetylbis(mercaptoethylimine)nickel has been reported (Q. Fernando and P. J. Wheatley, *Inorg. Chem.*, **5**, 1726 (1966)); this species could in principle be considered the neutral parent of a three-membered electron-transfer series with  $z = 0, -1, -2$ . The large standard deviations of reported distances in the C<sub>2</sub>N<sub>2</sub> chelate ring, common to this species and M(gma), preclude conclusions relative to delocalization in this ring.

(30) K. A. Jensen and J. F. Miguel, *Acta Chem. Scand.*, **6**, 189 (1952).

(31) Note that valence bond structures can be written for Ni[o-C<sub>6</sub>H<sub>4</sub>(NH)S]<sub>2</sub><sup>+</sup> and Ni[SC(Ph)NNH]<sub>2</sub><sup>+</sup> which are entirely analogous to those for [NiS<sub>4</sub>C<sub>4</sub>R<sub>4</sub>]<sup>+</sup> (cf. ref. 14).

(32) The structure of the related complex, 2-keto-3-ethoxybutyraldehydebis(thiosemicarbazone)copper has been briefly reported (M. R.

zen solutions of sulfur and sulfur-containing  $s^{24}$  and in irradiated single crystals of sulfur-containing compounds,<sup>35</sup> the largest anisotropic value observed is 2.066.<sup>36</sup> Furthermore, in radicals where it is highly probable that the odd electron is essentially localized on the sulfur atom,  $\langle g \rangle$  has not been observed to exceed 2.03<sup>34</sup> and is frequently  $\sim 2.01$ . For example in the radical anion of 1,8-naphthalene disulfide, 2.0110; extended Hückel calculations predict complete localization of the odd electron on the atoms.<sup>37</sup> Likewise, in the species which is applied to the 2,4,6-tri-*t*-butylphenylmercapto radical, hyperfine splitting and  $\langle g \rangle = 2.0104$  are found.<sup>38</sup> We conclude that the larger  $g$ -value anisotropies and isotropic  $g$  values of the complexes in Table II are indications of appreciable admixture of  $d$  orbitals of the metal in the wave function of the odd electron. Particularly remarked, the anisotropic and isotropic  $g$  of  $\text{Ni}(\text{mnt})_2^-$ , as well as the  $^{61}\text{Ni}$  hyperfine  $g$  tensor, can be quantitatively accounted for by  $3g$  ground state and a relatively large degree of ligand covalent bonding.

**Bis-Bidentate  $[\text{M}-\text{N}_2\text{S}_2]^+$  Complexes.**  $\text{Ni}[\text{o}-(\text{H})\text{S}]_2^-$  and  $\text{Ni}[\text{SC}(\text{C}_6\text{H}_5)\text{NNH}]_2^-$  were prepared by sodium amalgam reduction in 2-methyltetrahydrofuran but were not isolated. Both ions give strikingly similar epr spectra with the general features i and ii above. Hyperfine splitting was not observed in solution. Because of the close relationship between the  $g$  values of these complexes and those in II, it is concluded that a  $^3B_g$  ground state (as  $C_{2h}$  symmetry) is very probable for these  $[\text{Ni}-\text{S}_2\text{S}_2]$  species.<sup>39</sup>

**$\text{M}(\text{gma})^-$  Complexes.**  $\text{Ni}(\text{gma})$  has been reduced by controlled potential electrolysis in DMSO-solution and by treatment with sodium amalgam in 2-methyltetrahydrofuran. Both methods generate complexes with  $g$  values only slightly above the free-electron value (2.0023) and with a  $g$  anisotropy markedly less than those of bis-bidentate  $[\text{M}-\text{N}_2\text{S}_2]^+$  or  $[\text{M}-\text{S}_2\text{S}_2]^+$  complexes. Further, the analyzed salt  $(n\text{-Bu}_4\text{N})[\text{Ni}(\text{gma})]^-$  in DMSO- $\text{CHCl}_3$  solution or in a freshly prepared  $\text{CHCl}_3$  solution gives isotropic and anisotropic  $g$  within experimental error of those obtained by chemical or chemical reduction of  $\text{Ni}(\text{gma})$ . Usually, borohydride reduction of  $\text{Ni}(\text{gma})$  was found to produce  $\text{Ni}(\text{gma})^-$ .<sup>16</sup> This is now known to be the case and the product obtained has been identified as the bridge-hydrogenated species 14a

or 14b,<sup>16</sup>  $\text{Ni}(\text{H}_2\text{gma})^-$ . The borohydride reduction product is reported<sup>16</sup> to have  $\langle g \rangle = 2.051$ ,  $g_1 = 2.009$ ,  $g_2 = 2.027$ ,  $g_3 = 2.119$ , values very similar to those of the bisbidentate  $[\text{Ni}-\text{N}_2\text{S}_2]^+$  species.
